Fig. 2a). The curves are smoothed by running averaging over three terms.

Left-handed subunit helix in flagellar microtubules

ONE of the problems encountered in the study of a small negatively stained biological object by electron microscopy concerns the uncertainty in the distribution of stain around the object. If the particle is considered broadly as having two 'sides' one in contact with the support film and the other not, then the staining conditions may produce an image which represents one or other of the two surfaces or both sides together. Generally, the degree of contrast lies somewhere between these extreme cases¹. Unless there is a differential staining of one side with respect to the other and an unambiguous distinction between the near and far sides can be made it is generally impossible to determine the right or left-handedness of an object. (Moody² has however been able to demonstrate the right-handed sense of bacteriophage T4 sheath by the use of a convenient staining artefact).

A straightforward method for determining the sense of a helical object has been described recently by Finch³ in an investigation of negatively stained TMV particles, and in the present study this technique has been applied to the microtubules from the flagella of *Chlamydomonas reinhardtii*. The method depends on the fact that as a helix is tilted about an axis perpendicular to its own axis, either towards or away from an observer, the projected image becomes asymmetric about the centre line. More precisely, the helix lines at the edge of the image on one side become more inclined with respect to the axis and less so on the other. The difference in appearance between the two sides is most marked when the tilt is equal to the pitch angle of the helix which is, for a

microtubule, approximately 12° – 15° . This is the most obvious helix in the negatively stained structure and is defined as that with the smallest pitch passing through subunits in adjacent longitudinal filaments⁴.

A short section of central microtubule from a *Chlamydomonas* flagellum is shown in Fig 1. The microtubule, negatively stained with uranyl acetate, has been tilted towards (positive) the observer by 12° in the upper micrograph and in the opposite direction (negative) in the lower micrograph. The top end of the microtubule, as it appears in the

FIG. 1 A short section of negatively stained central microtubule from a *Chlamydomonas* flagellum tilted, by 12° , towards (+) and away (–) from the observer. The optical transforms are of the right (RHS) and left (LHS) hand side of each micrograph and the major 4 nm reflection is shown in each by an arrow. The reflection lies closest to the meridian for RHS+ and LHS– (particularly clear for the negative tilt) indicating a left-handed helix of subunits.

figure, moves towards the observer for positive tilt and away for negative tilt. Clearly the micrographs themselves do not reveal any distinctive change in pattern across the microtubule diameter but optical transforms of each half (RHS and LHS) of the two images are capable of resolving the differences. A strong reflection from the 4 nm axial periodicity in the microtubule^{4,5} is arrowed in each transform and the radial positions may be compared in the two transforms from each micrograph. (The presence of only one strong reflection close to the meridian in each pattern signifies predominant staining of only one side of the microtubule.) It can be seen that the reflection lies closest to the meridian for RHS positive and LHS negative and this is compatible with a left-handed helix³. The differences are small because of the flattening of the microtubule but are, nevertheless, distinct. Additional reflections further away from the meridian appear in some of the transforms and their relative positions also change with the degree of tilt. These can also, in principle, be used to determine the helix sense but as they correspond to families of subunit helices of greater pitch, the microtubule would have to be tilted through a considerable angle (40° – 50°) before any measurable change could be detected in the radial positions of the diffraction maxima. Since the image quality deteriorates rapidly with increasing tilt angle observations have to be restricted to the near-meridional reflections. Of the transforms so far examined those that contain discrete 4 nm reflections have shown consistently a left-handed helix of subunits, although no conclusive results have as yet been obtained for microtubules from sea urchin sperm flagella.

Once the helix sense has been determined it is also possible to infer from the 'sense' of the transforms which side of the microtubule is stained in a one-sided image. The diffraction patterns in Fig 1, and the majority of those obtained, indicate for this preparation predominant staining of the surface away from the specimen grid.

Suppressor cells in normal immunisation as a basic homeostatic phenomenon

WHEN guinea pigs are treated with one dose of cyclophosphamide (CY, 300 mg kg⁻¹) 3 d before sensitisation with either ovalbumin in Freund's incomplete adjuvant (OA/FIA) or 2,4 dinitrofluorobenzene (DNFB), the resultant Jones-Mote or contact skin reactions elicited 1 week later are increased in intensity and induration and prolonged as compared to control animals^{1,2}. We have postulated that CY pretreatment depletes a population of cells which normally modulate contact sensitivity and Jones-Mote reactions^{1,2}. If CY was depleting a population of suppressor cells normally present at the time of sensitisation, the passively transferred cells from these animals should be more reactive than if there was no CY given to the donors. Passive transfer of spleen or peritoneal exudate cells (PEC) from animals sensitised with OA/FIA 8 d earlier caused more intense and more indurated reactions in normal recipients when donors had been pretreated with CY 3 d before the OA/FIA sensitisation, when compared with those reactions transferred from sensitised animals which had not received CY (S. I. K., D. P., and J. L. T., unpublished) (Fig. 1). We used the following model for the assay of suppressor cells. Guinea pigs, treated with CY 3 d before immunisation with OA/FIA, served as cell recipients 8 d later. They were then potentially susceptible to the effect of suppressor cells which they were lacking.

The recipient animals in all experiments were 450–500 g albino Hartley strain guinea pigs. They were all treated

* 24 h after skin test with 100 μ g OA (10^{-1} mm).† 3×10^8 spleen cells and 2×10^8 PEC heat killed before transfer.

with 300 mg kg^{-1} CY intraperitoneally (LD_{50-50}) 3 d before footpad injection with 1 μ g OA in FIA (evenly divided in each footpad). Eight days after sensitisation, these animals received an intravenous injection of thrice washed spleen cells (3×10^8 viable) or PEC (2×10^8 viable) from sensitised donors. Skin tests with 100 μ g OA were performed 1 h after cell transfer and the skin test reactivity was assessed as described previously³. One group of CY treated OA/FIA sensitised animals always served as controls and did not receive any cells.

When recipient animals received either spleen cells or PEC from donors sensitised with 1 μ g OA in FIA 8 d before, the skin test reactions were markedly reduced as compared to control animals not receiving cells and to those recipients receiving cells from animals sensitised with 1 μ g bovine gamma globulin (BGG) in FIA 8 d before (Fig. 2). When the donor animals were treated with 300 mg kg^{-1} CY 3 d before immunisation with OA/FIA and the cells taken for transfer 8 d later, the skin tests of the recipient animals were increased as compared with the control animals not receiving cells and with the animals receiving cells from OA/FIA sensitised animals which had not received CY (Fig. 3). This is explicable on the assumption that, as a result of CY pretreatment of the donors, the transferred cells lacked a population of suppressor cells. The increase in reactivity would therefore result from the transfusion of effector cells alone. The results of all assays for suppressor cells using this system are shown in Table 1. Cells taken from animals 14 d after immunisation with OA in FIA and transferred into CY pretreated OA/FIA animals also decreased the reactivity of the recipient animals. Cells taken from animals immunised with 10 μ g OA in Freund's complete adjuvant (FCA) suppressed the reactivity of the recipient animals. When cells from donors immunised 8 d earlier with OA/FIA were killed by heating at 56° C for 40 min (spleen < 1% viable, PEC < 2% viable as assessed by Trypan blue exclusion) they did not suppress the reactivity of the recipient animals. Other control experiments demonstrated that cells taken from OA/FIA animals had the same reactivity in recipients whether or not the recipients were treated with CY 11 d before cell transfer.

These findings demonstrate that during normal sensitisation with OA in FIA or FCA, suppressor as well as effector cells are stimulated. The suppression of skin test reactivity in this system depends on live cells and is immunologically specific. Cells from animals sensitised to OA in FIA 7 or 8 d previously can transfer Jones-Moté type reactions to normal animals. The reactions observed start 6–8 h after skin test, reach a peak at 24 h and are markedly reduced or gone at 48 h.

It is difficult to demonstrate delayed hypersensitivity (Jones-Moté) reactions in animals sensitised with OA/FIA 14 d previously as, owing to the presence of humoral antibody, they show strong Arthus reactivity. Lymphocytes from these animals cannot transfer delayed type reactivity. If suppressor cells and antibody production are not allowed to develop as a result of CY pretreatment, however, guinea pigs show delayed hypersensitivity which can be transferred with lymphocytes to normal recipients (S. I. K., D. P., and J. L. T., unpublished). Thus, using the optimal immunisation schedule for the generation of Jones-Moté reactions⁴, effector as well as suppressor cells are normally demonstrable 7 or 8 d after sensitisation, whereas the balance of suppressor to effector cells 14 d after immunisation may be such that no delayed hypersensitivity reaction is demonstrable. This effector-suppressor balance may explain the evanescence of the Jones-Moté type of delayed hypersensitivity reactions. The demonstration of cells able to suppress delayed hypersensitivity reactions 14 d after sensitisation with OA in FIA may also explain the findings of Loewi, Holborow and Temple⁵ who showed that split tolerance or immune deviation to OA (no delayed hyper-

Fig. 2 Transfer of PEC and spleen cells. Donor cells taken 8 d after sensitisation with OA or BGG in FIA. () number of recipients.

sensitivity reaction while antibody production is normal) follows 14 d after immunisation with OA in FIA. Although we had not anticipated the ability of cells from animals immunised with OA in FCA to suppress delayed hypersensitivity reactions, their presence is in keeping with our earlier studies². It may be that many more effector cells are stimulated by OA in FCA as compared to OA in FIA and when suppressor cells are depleted by CY pretreatment of OA/FCA animals the effect of this depletion is much more difficult to demonstrate.

What are these suppressor cells? Our earlier studies on the morphological and functional effects of one dose of CY show depletion of B cell areas from lymphoid tissues of mice and guinea pigs and a decrease in antibody formation^{1,2,6}. There is also a selective increase in θ -positive cells in CY-treated animals⁷. All this would indicate that CY has a selective effect on B lymphocytes and would favour the postulate that the suppressor cells are B cells as they are depleted with one dose of CY before sensitisation. CY may also affect short lived T lymphocytes however, and for this reason we thymectomised adult guinea pigs, sensitised them 6 weeks to 3 months later and found no change in skin test reactivity to OA or DNFB 7 d after sensitisation with OA/FIA or DNFB. By extrapolation from findings in the mouse, adult thymectomy should deplete short lived or T₁ cells⁸ and, if these were the suppressor cells, we should see changes in the skin test reactivity. The assumption that this procedure (adult thymectomy) should have the same effect in the guinea pig as in the mouse may be wrong.

The evidence thus favours the existence of B lymphocyte suppressor cells being stimulated during normal immunisation. These suppressor cells are acting at the efferent end of the delayed hypersensitivity reaction as skin tests are performed just 1 h after intravenous injection of cells. Several possibilities exist as to how this suppression may occur. First, in all the normal immunisation systems in which suppressor cells have been demonstrated there is eventual antibody production and it is possible that small amounts of antibody coat cells which then come into contact with the antigen and compete with effector cells for antigen. Moreover, it has not been possible so far to dissociate suppressor cell

from humoral antibody formation. Second, the suppressor cells may liberate substances which inhibit the effector cells or their products. Third, suppressor cells may liberate substances which are chemotactic for other cell types which might modulate the normal reaction. In this regard we have recently confirmed the work of Dvorak *et al.*⁹ who have demonstrated that basophils are found in high percentages in all of these skin test reactions when elicited early after immunisation.

Effective cell separation techniques for guinea pig cells will help determine, with greater certainty, which lymphocyte subpopulation is responsible for the suppression of delayed hypersensitivity reactions during normal immunisation. The mechanisms⁴ by which this suppression occurs could then be more easily determined.

Pyrrolizidine ester alkaloid in danaid butterflies

THE dihydropyrrolizines (I-III, Fig. 1a) found in the hair-pencil secretions of male butterflies of the sub-family Danainae¹⁻⁵ and shown in one instance to be an important courtship pheromone⁶, are closely related to the hepatotoxic dihydropyrrolizine metabolites of the pyrrolizidine alkaloids^{7,8}. We have previously adduced evidence which points strongly to these hair-pencil constituents having their origin in plant alkaloids (or their metabolites) ingested by the adult insects⁵. Thus, there are a number of reports of adult male danaid butterflies being strongly attracted to, and sometimes feeding on, dead and withering plants containing pyrrolizidine alkaloids⁵. With one species, *Danaus chrysippus petilea* (Stoll) we have shown⁵ that when dihydropyrrolizine-deficient laboratory-reared butterflies are given access to one such alkaloid containing plant, *Heliotropium amplexicaule* (Vahl), they soon acquire the dihydropyrrolizine ketone (I) which is normally found on the hairpencils of this species.

We report here the first identification of a pyrrolizidine ester alkaloid, lycopsamine, in hair-pencil extracts of two Australian danaid species captured in the field. This alkaloid is typical of those occurring in the plants to which male danoids show specific attraction. The additional molecular

complexity of the alkaloid compared with the dihydropyrrolizine phenomones and the fact that the type of branched chain acid esterifying the pyrrolizidine aminoalcohol is unique in nature to these plant alkaloids, leaves no doubt that the alkaloid is of plant origin. Its occurrence in hairpencil extracts is regarded as confirming that the dihydropyrrolizine phenomones are metabolites of plant alkaloids of the pyrrolizidine group.

Five male *Danaus hamatus hamatus* (Macleay) and twelve male *Euploea tulliolus tulliolus* (Fabricius) were captured at Wallaville, Queensland. The hairpencils of individual butterflies were removed and extracted with 30 μ l of methanol. The extracts were then individually examined, before and after conversion to trimethylsilyl derivatives, using an integrated gas chromatograph-mass spectrometer. The extracts of ten *Euploea tulliolus tulliolus* and all five *Danaus hamatus hamatus* contained the dihydropyrrolizines previously identified in these two species³ as well as a number of other components (Fig. 2). One component, common to the extracts of both species (Fig. 2a, peak 2 and Fig. 2b, peak 3) gave a mass spectrum corresponding to a viridifloric or trachelanthic acid ester of retronecine or heliotridine esterified at the C₆ hydroxyl.

FIG. 1 a, The dihydropyrrolizines. I, R = $-\text{CH}_3$, R' = $-\text{O}$; II, R = $-\text{CHO}$, R' = $-\text{OH}$; III, R = $-\text{CHO}$, R' = $-\text{H}$. b, IV, R = β -OH ((-)-trachelanthic acid); V, R = β -OH ((+)-trachelanthic acid); VI, R = α -OH ((+)-trachelanthic acid); VII, R = β -OH ((+)-viridifloric acid); VIII, R = α -OH ((+)-viridifloric acid). (For explanation see text.)

Cochromatography of hairpencil extracts with authentic samples of the five known pyrrolizidine alkaloids (Fig. 1b) in this category⁹, that is indicine (retronecine, (-)-trachelanthic acid) (IV); intermedine (retronecine, (+)-trachelanthic acid) (V); rinderine (heliotridine, (+)-trachelanthic acid) (VI); lycopsamine (retronecine, (+)-viridifloric acid) (VII); and echinatine (heliotridine, (+)-viridifloric acid) (VIII), indicated that the butterfly alkaloid was lycopsamine (VII). The chromatographic retention time and the mass spectrum of the trimethylsilylated butterfly alkaloid also corresponded with those of authentic bis-trimethylsilyl lycopsamine.

Lycopsamine has been isolated from *Amsinckia hispida* (Ruiz et Pav.) I. M. Johnston, A. *intermedia* Fisch. et C. Mey., A. *lycopsoides* Lehm¹⁰ and *Echium lycopsis* L. (J. L. Frahn and J. A. Mills, personal communication). These plants are widely established in south-eastern Australia but occur either rarely (*Amsinckia*) or sparsely (*Echium*) in Queensland, mostly in the Darling Downs region. The known occurrences nearest to Wallaville are 180 miles distant for *Amsinckia* and 50 miles distant for *E. lycopsis* (S. L. Everist and V. K. Moriarty, personal communication). Other species which probably contain or are known to contain, this type of alkaloid occur more commonly in the Wallaville district. These include *Heliotropium amplexicaule* which is already known to attract adult male danaiids⁵ and to contain

(1) 1-methyl-7-oxo-6, 7-dihydro-5H-pyrrolizine (I); (2), the monotrimethylsilyl derivative of 1-formyl-7-hydroxy-6, 7-dihydro-5H-pyrrolizine (II); (3), the bis-trimethylsilyl derivative of lycopsamine (VII). (see Fig. 1).

indicine⁹ (IV), a diastereoisomer of lycopsamine. These plants are now under investigation, as possible sources of the hairpencil alkaloid.

The requirement by male butterflies of the subfamily Danainae for pyrrolizidine alkaloids is an extraordinary fact which we believe is a pointer to their evolutionary development.

Population estimates from recapture studies in which no recaptures have been made

THE number of animals in a population can be estimated from the proportion of individuals in a sample which have been captured previously¹⁻³. Animals which have been captured previously may be recognised by some method of marking. If the population is very large relative to the size of the samples, no marked individuals might be recaptured, because the probability of capturing any of the few marked animals is very small. Marked animals may, however, fail to be recaptured even if the population is quite small, because of random sampling error. It has not been realised before that a useful estimate of population size can be made even when no animals have been recaptured.

Suppose that a animals from a total population of size N have been marked and released. On a subsequent occasion, n animals are captured, none of which bear marks. If it is assumed that the usual conditions of recapture analysis are met, then the probability that the first animal to be captured will be unmarked is $(N - a)/N$. Similarly, the probability that the second animal to be captured is unmarked is $(N - a - 1)/(N - 1)$. Thus, the probability that all n captures are unmarked is:

$$\begin{aligned}
 P &= \frac{(N - a)}{N} \cdot \frac{(N - a - 1)}{(N - 1)} \cdots \frac{N - a - (n - 1)}{N - (n - 1)} \\
 &= \frac{(N - a)! / (N - a - n)!}{N! / (N - n)!} \\
 &= \frac{(N - a)! (N - n)!}{N! (N - a - n)!}
 \end{aligned}$$

By inserting trial values of N into this equation, one can obtain the probability P that the population is not larger than this trial value. The distribution of the probability is shown in Fig. 1, for an example in which eight marked animals have been released and several animals have subsequently been captured, none of which bear marks. As expected, the curves become asymptotic with $N = \infty$ at $P = 1$ and with $N < (n + a)$ at $P = 0$. I would suggest that in studies of small populations, an appropriate minimum estimate of population size may be made by solving the equation given above for N , by iteration, with $P = 0.5$. The meaning of this estimate is that the probability that the population

Fig. 1 Probability distribution for an example described in the text.

is larger than the estimate is equal to the probability that it is smaller. If 95% limits are required, they can be obtained by solving for N with $P = 0.025$ and $P = 0.975$ respectively.

Restoration of libido in castrated red deer stag (*Cervus elaphus*) with oestradiol-17 β

THE role of oestrogens in male reproduction remains an enigma. It is known that the stallion^{1,2} and the boar³ excrete enormous amounts of oestrogen in their urine, and that this is of testicular origin^{4,5}; more modest amounts of oestrogen are secreted by the testis of the bull⁶, rat⁷, and man⁸⁻¹⁰. Interest in male oestrogen was recently reawakened by the discovery that the hypothalami of rats, rabbits, monkeys and men are capable of aromatising testosterone to oestradiol-17 β (ref. 11). This indicated that oestradiol-17 β might be the central mediator of androgenic effects, an idea that is beginning to receive support from a number of different experiments. For example, it has been established that newborn female rats can be sterilised equally effectively by small doses of either androgen or oestrogen¹². In addition, the anti-oestrogen MER-25 will effectively inhibit this neonatal sterilisation even when it has been induced by testosterone¹³. It also seems significant that androgens which cannot be metab-

olised to oestrogen, such as dihydrotestosterone (DHT), have no apparent effect on the brain¹²⁻¹⁶, although they are potent stimulators of male secondary sexual characteristics. Whilst DHT alone cannot restore libido to a castrated male rat, the addition of a few microgrammes of oestradiol will restore libido completely^{17,18} and, recently, it has been shown that pharmacological doses of oestradiol benzoate are sufficient to restore all components of male reproductive behaviour to castrate male rats²⁰.

We decided to investigate the effects of oestradiol-17 β on the social and sexual behaviour of free-living, wild red deer stags on the island of Rhum, off the west coast of Scotland. Although red deer may seem rather unusual experimental animals, they are particularly suitable for this type of investigation for a number of reasons. Changes in social hierarchy can easily be quantitated within the bachelor group in which stags associate for most of the year^{21,22}. Sexual behaviour is virtually confined to the rut in September and October, in which the final act of copulation is preceded by several weeks of elaborate and well-defined behavioural displays. These include roaring, flehmen, wallowing in peat hags, thrashing the herbage with the antlers, repeated 'flicking' of the penile sheath, protrusion of the penis with emission of spurts of urine which soak the ventral body wall and impart the characteristic strong rutting odour, migration from the home range to a traditional rutting area, herding of groups of hinds, and intense aggressive displays frequently leading to fights with other stags^{21,22}. Testosterone appears to exert a dose-dependent inductive effect on the level of social aggression, whereas it has a permissive effect on sexual behaviour, which can only be exhibited at certain times of the year²². Castration of a stag even only a few weeks before the rut will eliminate every component of sexual behaviour, which can be fully restored with an implant of testosterone²². Finally, the antlers of the stag serve as a convenient external indicator of its endocrine state, as antler casting in the spring is a result of a testosterone deficiency, and can be produced experimentally by castration, whereas cleaning of the velvet from the growing antler in late summer is a consequence of rising testosterone levels²².

We carried out experiments on two intact and three castrated adult stags, each of which was given a subcutaneous implant of 100 mg oestradiol-17 β (Organon) at various times of the year; castrate and intact animals were implanted in early January and late August, and another castrated animal was implanted in early July.

The intact stags started to roar about 3 weeks after receiving the implants, and they kept this up for many months, whereas untreated normal stags never roar outside the rut. There was no initial change in the social rank of the implanted animals, and at no time did they show any signs of oestrous behaviour²³, or attract the sexual attention of other stags. They rutted normally at the usual time, but they failed to cast their antlers for at least 2 yr, giving some indication of the longevity of the implants. They gained a temporary advantage over normal stags when the latter were

casting their old antlers and growing new ones in velvet, and so they rose temporarily in the hierarchy.

The castrated animals responded to the implants by cleaning the velvet from their antlers 3 to 4 weeks later, and starting to roar. They then went on to show most of the components of rutting behaviour, including flehmen, wallowing, thrashing, flicking the penile sheath, and urination from the protruded penis. They also began to herd hinds in a manner characteristic of a rutting stag, and displayed and fought with other stags. They failed to develop a male rutting odour, however, and failed to migrate out of their home range, nor did they sustain their rutting activity for more than a few hours at a time.

Because of the practical difficulties in observing the mating behaviour of the castrates in the wild, one castrate was implanted with oestrogen whilst confined to a 15 hectare fenced enclosure on Rhum. This animal had spent a number of years in the enclosure whilst intact but vasectomised, when he had shown full normal libido. Following castration in August 1972, all components of male sexual behaviour immediately disappeared, and he cast his antlers and even became subordinate to a group of hinds in the same enclosure. He was implanted with 100 mg oestradiol-17 β on July 8, 1973, and cleaned his antlers during the first week of August. He then rapidly reasserted his dominance over all the hinds, but remained subordinate to two intact stags. When these stags were removed from his enclosure, the castrate immediately took possession of the hinds, showing the complete repertoire of rutting behaviour including mounting of hinds in oestrus, intromission, and ejaculation. At the height of the rut in October the castrate engaged in a vicious and prolonged fight with one of the intact stags that had been allowed temporary access to his enclosure.

To establish whether this resurgence of sexual activity was a direct effect of the oestrogen implant, or a result of androgen secretion by the adrenal glands or a testicular rest, the castrate was killed on October 22 and subjected to a detailed post-mortem examination; the results were compared with those from normal stags and an untreated castrate killed at the same time of year²⁴ (Table 1). Peripheral blood samples were collected and oestradiol-17 β and testosterone measured by radioimmunoassay. The weight of the oestradiol implant at autopsy was 89.4 mg, indicating that a total dose of 10.6 mg had been absorbed over a period of 106 d, giving an average daily release of 100 μ g. The concentration of oestradiol in the peripheral blood of this animal was 38 pg ml⁻¹, whereas it was undetectable (< 5 pg ml⁻¹) in the peripheral blood of an intact stag during the rut.

No testosterone could be detected in the peripheral blood of the castrate (< 0.1 ng ml⁻¹), in striking contrast to the levels in intact rutting animals (8.9 ng ml⁻¹), so it seems safe to conclude that the rutting behaviour of the castrate was indeed produced by oestradiol-17 β (or some metabolite) acting directly on the brain. The oestrogen had also apparently caused some stimulation of the seminal vesicles and limited fructose synthesis, but it had completely failed

TABLE 1 Comparison of hormone levels and secondary sexual characteristics of intact stags, a castrate stag, and an oestrogen implanted castrate stag in October.

	Combined weight of seminal vesicles (g)	Fructose content of seminal vesicles (mg/100 g)	Peripheral plasma oestradiol-17 β (pg ml ⁻¹)	Peripheral plasma testosterone (ng ml ⁻¹)	Neck girth (cm)	Mane length (cm)	State of antlers	Presence of rutting odour
Intact stags	68* (4)	285* (4)	< 5	8.9* (5)	64* (6)	10* (6)	Hard horn	+++

* indicates that the measurement is a mean, figures in parentheses indicate sample size²⁴.

to stimulate the development of the rutting odour, and the neck mane and neck musculature were only slightly developed.

In conclusion, this study has demonstrated that in the red deer stag, microgramme quantities of oestradiol-17 β are as effective as milligramme quantities of testosterone in restoring full sexual behaviour to castrated animals, and in producing antler changes. But unlike testosterone, oestrogen does not seem to have a direct effect on the induction of social aggression. Neither hormone is capable of producing sexual activity out of season in intact stags.

It remains to be discovered for the generality of mammals whether testicular oestrogens or oestrogens formed from testosterone in the central nervous system are essential for eliciting components of male sexual behaviour.

We thank the Natural Environmental Research Council and the Wellcome Trust for financial support, and the Nature Conservancy for experimental facilities on the Isle of Rhum.

Erratum

IN the article "Intraplate Earthquakes, Lithospheric Stresses and the Driving Mechanism of Plate Tectonics" by Lynn R. Sykes and Marc L. Sbar (*Nature*, **245**, 298; 1973), Fig. 3 was reproduced on too small a scale for the salient points to be clear and so it is reproduced again here.

book reviews

Essays on Needham and China

Chinese Science: Explorations of an Ancient Tradition. Edited by Shigeru Nakayama and Nathan Sivin. Pp. xxxvi+334. (MIT East Asian Science Series, Vol. 2.) (MIT: Cambridge, Mass and London, 1973.) £5.65.

THE purpose of this compilation of essays, according to the preface prepared by the second editor (Sivin) is twofold: to provide perspectives on the work of Joseph Needham, to whom the volume is dedicated, and to provide a sample of representative 'explorations' of Chinese science. In offering to relieve the reviewer of the burden of reading each essay, the editor invites evaluation of his book in terms of the purposes he sets out.

Because the history of Chinese science and technology has been dominated in the West by the work of Joseph Needham, the efforts to put it in perspective have been few, indeed. The measure of *Science and Civilisation in China* is best taken in terms of its purpose, which Needham himself describes in his essay in the present volume:

"One of the greatest needs of the world in our time is the growth and wide dissemination of a true historical perspective, for without it whole peoples can make the gravest misjudgments about each other. Since science and its applications dominate so much our present world, since men of every race and culture take so great a pride in man's understanding of Nature and control over her, it matters vitally to know how this modern science came into being . . . distinctively modern science did in fact come into being only in Western Europe during the 'scientific revolution' of the fifteenth and sixteenth centuries, culminating in the seventeenth. But this is indeed far from being the whole story, and to tell this part of it alone is to be deeply unjust to the other civilizations."

Needham has begun a preliminary exploration, according to the present editor, putting forward tentative hypotheses, rather than providing a definitive summary of the Chinese scientific and technical traditions. The first three essays evaluate Needham's work from different perspectives. To Derek de Solla Price, it is a "definitive classic", a systematic presentation of the raw material for generations of scholars and a point of departure for all sub-

sequent work. Shigeru Nakayama analyses the elements in Needham's thought in relation to his personal life and his views as a biochemist, which have influenced his interpretation of the history of Chinese scientific and technical development: an evolutionary rather than a mechanistic viewpoint; a preference for synthesis over analysis; and dialectical materialism. These, in Nakayama's view, have led to "a number of insecurely based speculations", which contradict both conventional scholarship and historical facts. Summarising the views of Needham's critics and analysing the more controversial of Needham's views, Nakayama evaluates *Science and Civilisation in China* as a body of "heuristic suggestions and unelaborated ideas", which remain to be synthesised by future scholars. It is in this sense that Needham's work is a "determinant" of modern awareness of China. A. C. Graham comments on the development of Needham's response to the problem of why there was a Scientific Revolution in Europe but not in China, from a "fairly straightforward Marxist answer influenced by the early Wittfogel" [in *On Science and Social Change* (1944)] to "his sociological explanation but in a much more developed and refined form, for which he acknowledges a debt to Jean Chesneaux and Andre Haudricourt". Needham's thought on Chinese scientific development no more springs from a single origin than the modern science whose roots he traces to a number of cultures and societies.

The remaining six essays, by Mitukuni Yosida, Kiyosi Yabuuti, A. C. Graham and Nathan Sivin, Ho Peng Yoke, Beda Lim and Francis Morsingh, William C. Cooper and Nathan Sivin, and Saburo Miyasita, represent current scholarship based, like Needham's, on the use of primary documents, of "high intellectual and critical standards", in the editors' view. The body of scholarship which can meet such criteria is admittedly small, though its composition is ecumenical. An important contribution of this volume is in presenting representative works by Japanese scholars, which until now have rarely been accessible to the non-specialist in English translation. It is, as the editors acknowledge, regrettable that contemporary scholarship in China itself is not represented in this collection, but it is also to be regretted that the

reasons for this lack and, indeed, the present state of Chinese scholarship in this field are not discussed in the preface.

For the layman about to begin his own explorations in Chinese science, these papers provide a frame of reference for the monumental work of Joseph Needham by "de-mythologizing" the role of one man in studies of the science and technology of traditional China. With this collection of essays as a beginning, and further guided by the introductory bibliography with which this volume concludes, the layman's understanding of Chinese science should no longer have to be "determined" by Needham's work to the same extent. On the other hand, one of the motivations for the compilation of these essays was the editor's view that "everyone who is concerned about the central problems of our time has a stake in the deeper understanding of science in ancient China". Of the scholarship which deepens understanding of traditional Chinese science, it is surely that of Joseph Needham which extends understanding to those whose concern is the present.

G. C. DEAN

Fish chromosomes

Fish Chromosome Methodology. By Thomas E. Denton. Pp. vii+166. (Thomas: Springfield, Illinois, 1973.) n.p.

THE chromosomes of fishes are, characteristically, small in size and large in number. For these reasons they are difficult to handle and this book represents, in the main, a survey of cytological methods for the preparation and study of fish chromosomes.

One may well ask what justification there is for a book devoted to fish chromosomes alone. First, from a practical standpoint, there is unquestionably a big future in fish breeding for which a thorough knowledge and understanding of the chromosomes will be essential; particularly, as seems likely, where hybridisation between species may prove useful. Second, from a strictly cytological standpoint, there are many reports among fishes of Robertsonian changes associated with divergence in chromosome number between species within genera, between and within populations of the same species and even between somatic cells within individuals. It is by no means clear whether such widespread chromosome numerical variation,

in the Salmonidae for example, reflects some special structural organisation of the chromosomes facilitating breakage and rejoining in centromeric regions or, alternatively, is the consequence of special and intensive kinds of selection pressures which confer high premium upon change in linkage relations within complements.

Until the techniques for investigating fish chromosomes are improved these and other questions will remain unanswered. As the author implies the most promising development is the culture of leukocytes, along the lines which revolutionised mammalian cytology during the past two decades. So far the technique has proved only partly successful with fishes. In the meantime the book gives a comprehensive account of the many other techniques available. Also useful is the extensive list of chromosome numbers, involving 481 species. For the rest the book is a bit of a hotch-potch, dealing with subjects ranging from elementary cytology ("autosomes are composed of two strands or chromatids joined together by a centromere") to the use of the light microscope and the evolution of the fish karyotype. For those working on fish chromosomes the survey of methods, the chromosome list and accompanying references are, in themselves, good reasons for buying the book.

H. REES

Skin and feather

Avian Anatomy: Integument. By Alfred M. Lucas and Peter R. Stettenheim. Part 1 pp. iv+1-340; part 2 pp. x+341-750. (Agriculture Handbook 362: US Department of Agriculture, in cooperation with Michigan Agricultural Experiment Station, Michigan State University.) (US Government Printing Office: Washington, DC, 1972.) \$13 per 2 part set.

THE authors of this work point out that "even today there has not yet been published a complete description of any species of bird, either wild or domestic". It was to fill this gap, for the benefit of pathologists working on poultry diseases, that the basic studies began, nearly 30 years ago, of which these two volumes are an outcome. The Avian Anatomy Project, of which Professor Lucas is director, plans to issue a series of handbooks covering all organ systems. If the standard of those that are to come equals the first, this long-continued and costly undertaking will be fully justified.

There have necessarily had to be some limitations in the scope of the work. The main limitation is that, although the treatment of descriptive anatomy is full and critical, no attempt has been made at a full and critical treatment of special problems confront-

ing physiologists, pathologists and general ornithologists who will use these volumes for reference. The subject matter of the two volumes under review is also limited: treatment of skeletal muscles, ligaments, nerves, blood vessels and lymphatics is reserved for a later volume. The greater part of these two volumes is in fact devoted to pterylosis and ptilosis (the difference in the meaning of the two terms is carefully defined and discussed), feather structure (macroscopic and microscopic), feather development and growth, and other skin derivatives. The birds mainly dealt with, in addition to the domestic fowl, are turkey, Pekin duck, *Coturnix* and common pigeon; but the great horned owl is also treated in some detail and there are plenty of references to other birds.

The mass of detail that is provided is made digestible, indeed very pleasantly and easily digestible, by the clarity with which it is presented, both in the text and in the figures, and by the care that has been taken to subdivide and index it. A great deal of care has been taken to devise a consistent and clear terminology, and I hope that it will be followed by all subsequent research workers in the field. A valuable final section on methods includes a most useful introduction to techniques of anatomical illustration.

The two volumes are well produced and excellently illustrated with a total of 422 figures, some in three or four colours. By present standards the price is remarkably low, so that many of those who are most likely to need them should be able to buy them. All zoological libraries should possess a copy. As the authors point out in their introduction, "Descriptive anatomy, well done, does not become obsolete".

D. W. SNOW

Spectroscopy for rocks

Mössbauer Spectroscopy: An Introduction for Inorganic Chemists and Geochemists. By G. M. Bancroft. Pp. xii+252. (McGraw-Hill: Maidenhead, September 1973.) £6.95.

ABOUT two and a half years ago, a comprehensive review on Mössbauer spectroscopy was published. (N. N. Greenwood and T. C. Gibb, *Mössbauer Spectroscopy*, Chapman and Hall, London, 1971). Now, Professor G. M. Bancroft has published a textbook for undergraduates or postgraduates who are following courses in this subject. As the title suggests, the bias is towards applications of the technique to inorganic chemistry and geochemistry. This textbook for undergraduates and postgraduates is an effective complement to Greenwood and Gibb. At present not

many schools of chemistry provide courses in this subject but wherever Mössbauer spectroscopy is taught, the publication of a student's text will be welcomed.

The book commences with a chapter in which essential background material is presented and explained. The topics covered here include radioactivity, nuclear properties, the Doppler effect, and an account of the discovery of the Mössbauer effect. This short chapter is followed by a longer one dealing with the parameters that can be measured by Mössbauer spectroscopy. The isomer shift is introduced and explained and an account of the quadrupole interaction is given. Then magnetic hyperfine splitting is elucidated and a survey is given of the characteristic features of a useful Mössbauer isotope. This is followed by a chapter on how Mössbauer spectra may be obtained. Here one can find details of drives, sources, detectors, counting statistics, calibration, and computation of parameters using least-squares fitting programs. The use of Mössbauer spectroscopy as a fingerprint technique in inorganic chemistry is then discussed. This chapter is a set of case histories of successful applications of Mössbauer spectroscopy. Each example is carefully and critically explained.

From the earliest days of Mössbauer spectroscopy the variation in the precise energy of the absorption has been of use in understanding variations in electron density from compound to compound and the factors influencing this variation. In this book this parameter is called the centre shift and chapter 5 is devoted to a discussion of its correlation with the oxidation state of the Mössbauer element and the bonding scheme appropriate to it. Here and elsewhere in this book the author has gone to a lot of trouble to find illustrative examples involving as many different Mössbauer nuclides as possible.

Chapters 6 and 7 are the longest in the book and taken together comprise its hard core. The first of these concerns the relationship between the quadrupole splitting and the stereochemical arrangement of the groups about the absorbing atom. The second deals with the contribution made with the help of Mössbauer spectroscopy to a knowledge of the structure of rocks and minerals which contain iron. These chapters strongly reflect the research interests of the author: they are accordingly very detailed and comprehensive.

The remaining two chapters deal with the determination of site populations in silicate minerals and with the study of multi-phase assemblages such as lunar soils and rocks.

Each chapter incorporates a set of problems to which partial answers are provided. The book is well provided

with references. There are some useful appendices and an adequate index.

Research students using Mössbauer spectroscopy will find this book much more helpful than anything else available. It can be recommended without reservations to students taking courses in the subject. At today's prices, it is good value.

B. W. FITZSIMMONS

Past and present plants

Vegetation and Vegetational History of Northern Latin America. Edited by Alan Graham. (Papers presented as part of a symposium at the American Institute of Biological Sciences Meetings, Bloomington, Indiana, 1970.) Pp. xii+393. (Elsevier: Amsterdam, London and New York, 1973.) Dfl. 120; \$46.20.

THIS attractive volume does not, as its title suggests, cover the whole area between Mexico and Peru. Most of the material concerns Mexico, Panama and the Antilles, regions being actively studied by the workers whose papers are published here. That there is much more information for the whole region is shown by Graham's extremely valuable bibliography, which lists some 960 references dealing with the vegetational history of Latin America, and some review of the current situation throughout the area of the title would have been welcome.

Nevertheless, the book is a most rewarding mine of up to date information and ideas. The descriptions of modern vegetation illustrate several approaches, ranging from Porter's largely sociological survey of plant communities in Panama to the structural treatment of vegetation types in Vera Cruz by Gómez-Pompa, who furnishes a surprisingly useful dichotomous key for their identification and relates them to the prevailing ecological factors. Breedlove provides an elegant account of Chiapas, floristically the richest and most diverse of the Mexican provinces, relating the vegetation types to Beard's broader classification for tropical America, and Howard also describes the vegetation of the Antilles in structural terms. Howard further provides a statistical analysis of the distributions of taxa to illustrate the floristic groupings within the flora, particularly the different extra-Caribbean affinities of the floras of the Greater and Lesser Antilles. Similar approaches are used by Rzedowski to examine the relationships of the floras of arid regions in Mexico.

In some ways the palaeobotanical papers are more stimulating since they seriously consider the flaws in some current assumptions and techniques. Dilcher uses his incisive studies of the Middle Eocene floras of the Mississippi

delta to examine ways of overcoming the difficulties in deducing past climates and vegetation from the tolerances attributed to modern plants and points to the incorrect taxonomic affinities ascribed to many fossil floras, a topic repeatedly mentioned in the palaeobotanical papers. Barlett and Barghoorn, in describing climatic and vegetational changes in Panama during the past 12,000 years, summarise the controversy about evaluating changes in sea-level and demonstrate the greater difficulties of deducing climatic fluctuations from complex tropical vegetation as compared with the post-glacial history of mono-climax areas in North Temperate regions. Despite such problems, the power of palaeobotanical studies for tracing the history of modern floras is exemplified by Graham's demonstration that such temperate trees as *Alnus* and *Juglans*, now of disjunct occurrence through northern Latin America, gradually migrated southwards from the south-eastern United States, where they date from the Eocene, to reach northern South America by the latest Pliocene. Unfortunately, the vexed question of the means of dispersal is not discussed.

The book is well produced, excellently illustrated and, unhappily, boldly priced. It deserves to be widely read.

D. M. MOORE

Electronics made easy

Electronics in the Life Sciences. By Stephen Young. Pp. 198. (Macmillan: London and Basingstoke, August 1973.) £5.50 boards; £2.75 paper.

WHEN I visited Stephen Young in his laboratory in Edinburgh a few years ago, I was first struck by the size of his Faraday cage, and then, on entering the cage, by the variety of superbly engineered home-built equipment that he was using to record the eye movements of a small crustacean. Here was an engineer as well as a scientist, a man who took as much pleasure in designing and building equipment as he did in carrying out experiments. Now he has written a book, and a remarkably good book it is too, in which he explains, in a down-to-earth practical manner, what every good biologist should know about electronics. This approach may upset purists in the field of electronics, but it is just right for experimental biologists.

The book is thoroughly up to date with many of the circuits described incorporating integrated circuits, operational amplifiers and field effect transistors. Everything is explained from first principles with the aid of clear simple diagrams of which there are more than 250. The few criticisms that I have all concern minor errors and omissions. An earth line is omitted from Fig. 8.15; the

circuit shown in Fig. 5.52 cannot function as shown because the integrator output is the wrong sign to trigger the comparator; one is not told how to add capacitors in series or in parallel or told how to solder delicate components; a spot on an oscilloscope screen is used as a light source in such a way that it would burn a hole in the phosphor. But these are small points and detract little from the book as a whole. Indeed the book is by far the best of its type that I have read and I thoroughly recommend it to all biologists who wish to know how to design simple electronic devices or learn about the circuits on which their electronic equipment is based.

W. J. P. BARNES

Kimberlites

Lesotho Kimberlites. Edited by Peter H. Nixon. Pp. xii+350. 70 plates. (Lesotho National Development Corporation: Maseru, Lesotho, 1973.) R13; \$19.

ALTHOUGH in the past decade there have been numerous papers describing kimberlites and their xenoliths, there has not been a comprehensive volume on kimberlites in the West since the classic treatise of A. F. Williams in 1932 on the kimberlites of South Africa. In this we have lagged behind the Russians whose spate of monographs on the Siberian kimberlites have added much to knowledge of kimberlites. Now *Lesotho Kimberlites* provides a comprehensive study of a part of the South African kimberlite province on which there were previously comparatively few data.

Included within this book are the results of studies by geologists of the Overseas Development Corporation, the United Nations Development Programme, academic geologists from South Africa, Europe and the United States, and mining company geologists from South Africa. Within the book are accounts of the geology and petrology of individual diatremes and dyke swarms, and a wealth of new geochemical and mineralogical data. Although the title of the book may give the impression that this is an account of a relatively small area, the subject matter of many of the papers is of much more than purely local interest. For example, the papers on the discrete nodules and sheared peridotites from the Thaba Putsoa pipe have implications for plate tectonics and the break-up of Gondwanaland; and the papers on the Matsoku xenoliths, the petrofabrics of the peridotite suite xenoliths, and the study on the opaque oxides of the kimberlite groundmass, will all become standard references in

the kimberlite literature from now on.

Considering that twenty-eight authors have been involved in the writing of this book, the editor has maintained a creditable consistency of style. Criticisms are that there could have been more thorough cross referencing between papers, and there is repetition of data in various tables. These are minor criticisms, however, and do little to detract from the overall merits of the book. The book will appeal more to petrologists than to economic geologists since, although some kimberlites are the host rock of diamond, there are only two small sections concerning diamond. The volume is well produced and the reproduction of most plates (many in colour) is high. The book is very good value and is recommended to anyone interested in kimberlite and upper mantle geology.

J. B. DAWSON

Basis for separation

An Introduction to Separation Science. By Barry L. Karger, Lloyd R. Snyder and Csaba Horvath. Pp. xix+586. (Wiley Interscience: New York and London, November 1973.) £9.75.

SEPARATION science is a relatively new name for an important branch of analytical chemistry and though the name has probably been introduced to brighten the image of analytical chemistry there is no doubt that operations classed as separation are much more scientifically based than most of the other activities to which the word science has recently been attached. Be that as it may, the authors of this book have made a bold and largely successful attempt to treat separation processes from a fundamental point of view, at the same time recognising the great diversity of experimental techniques which can actually be used.

Chromatography is undoubtedly the most versatile, sensitive and most widespread separation technique in use today but it is arguable whether roughly half this book should have been devoted to chromatography leaving the same space to cover all other important techniques: extraction, distillation, crystallisation, membrane separation, electrophoresis, particle fractionation and mass spectrometry. The bias towards chromatography makes this book of particular value to chromatographers as it presents a unified account of this subject within a wider framework, but it may be less valuable to the chemist primarily interested in, say, zone refining or electrophoresis.

Balance aside, the really significant contribution made by the authors is their emphasis that the same basic physico-chemical principles apply to widely differing separation techniques.

These principles are outlined in the first of the three major sections of their book which covers the thermodynamic and molecular basis of distribution equilibria, the kinetics of mass transfer by diffusion and flow, and the operational aspects of the major separation methods. In the chapters of parts 2 and 3 there are repeated back references to part 1 reinforcing this emphasis on fundamentals.

Part 2 deals specifically with techniques based upon phase and distribution equilibria, and here the authors have wisely brought in outside experts to cover distillation, solvent extraction, crystallisation, ion exchange and exclusion processes, they themselves dealing with gas chromatography, liquid-liquid chromatography and liquid-solid adsorption chromatography. In part 3 they cover barrier separation processes, electrophoresis, particle separation and, very briefly, mass spectrometry.

Parts 2 and 3 present a series of reviews of uniformly high quality which contain enough theory for the basis of each technique in fundamental physical chemistry to be clear. Yet the theory does not obtrude and the book is most readable for all of its nearly 600 pages. Each chapter contains a useful bibliography listing full-length texts and the numerous original papers cited in the text.

As a chromatographer, I was particularly impressed by the authoritative and up to date treatment of the different forms of chromatography; in this respect the book is much more than an introduction and presents many new and original ideas.

This book will undoubtedly find an important place in the library of the analytical chemist and particularly in the chromatographer's, and it will provide a stimulus to the teaching of separation science. At 1.7 pence per page it is good value.

J. H. KNOX

Pyrethrum

Pyrethrum: The Natural Insecticide. Edited by John E. Casida. Pp. xvii+329. (Academic: New York and London, December 1973.) \$16; £7.70.

THIRTY years ago, a variety of insecticides of vegetable origin were in use; but virtually all of them except pyrethrum were gradually displaced as modern synthetic insecticides became available. Despite the well publicised adverse effects of these new pesticides, it is likely that they will be needed for some vital uses, for some time to come. But there is no doubt that the present climate of opinion is very favourable for pyrethrum as a non-persistent natural product; hence this book. The virtual restriction to natural pyrethrum

is perhaps unfortunate, in view of the highly promising synthetic pyrethroids recently developed in Britain.

The 17 chapters of the book examine the present knowledge of pyrethrum and its active constituents from various points of view. The first two papers, by industrial experts, trace the commercial history of pyrethrum and the present sources of production. There follow three excellent chapters on chemistry. The composition of pyrethrum extract from the flower heads and methods of analysis and assay are summarised by S.W. Head of the Pyrethrum Marketing Board of Kenya. M. Elliott and N. F. Janes then describe the stereochemistry of the active components. The existence of both geometrical and optical isomers as well as variations in structure make this a highly complex subject, relying in recent years on mass spectrometry and nuclear magnetic resonance, for confirmation of hypothetical configurations. J. Casida then deals with the biochemistry; both the synthesis of pyrethrins in the plant and their degradation pathways in animal tissues.

The next six papers deal with toxicology and pharmacology. These comprise summaries of information on, first, toxicity to mammals, then an excellent paper on the effects of synergists in regard to toxicity by I. Yamamoto, and a rather disappointing account of what is known of the actual mode of action. The three other papers in this section describe original investigations of the effects of pyrethrins on wildlife; some tests of its possible teratogenic, carcinogenic, mutagenic and allergenic action; and interactions with other drugs. In the following section, four chapters describe types of usage: for medical and veterinary pests, for agricultural, and for forestry insects. A chapter on residue and tolerance considerations (including two synergists as well as pyrethrum) is, for some reason, set in the "Summary" section. More appropriately, E. M. Mrak concludes by summarising the advantages and disadvantages of pyrethrum, leaning rather heavily towards the former.

Despite inevitable inequality of treatment, the book provides a good distillation of many complex matters as well as a useful source of references.

J. R. BUSVINE

Corrigendum

IN the book review "IQ and inequality" by Jinks and Eaves (248, 287; 1974), the sentence starting in paragraph 8, line 7 should read "Making E' applicable purely to offspring results in a significantly poorer fit to Jencks's data" instead of "...slightly poorer...".

science on television

US "Nova" less than super

Miranda Robertson

SUNDAY March 3 this year saw the first in the science series "Nova", an attempt by the WGBH-TV, Boston backed by some of the more important science grant-giving bodies, to popularise the activities of scientists. The material for the programme, which will be transmitted by most of the 234 stations of the public broadcasting service, will comprise hour-long feature films drawn from various sources and including some originating with WGBH-TV, which will produce the programmes with the cooperation of the American Association for the Advancement of Science.

A sample preview of two of the films was presented at the meeting of the American Association for the Advancement of Science in San Francisco at the end of February, just before the series was due to start. The sample comprised a BBC feature of the filming of wild life in Britain, and a WGBH-TV film on pre- and exobiology which, it cannot be denied, suffered by comparison.

To begin with, the BBC's colour was superior; and they had, in the pond and tree life of Oxfordshire, (if not in the bearded fauna of the Oxford Zoology department) the more photogenic subject. It is hard, after all, to imagine anything much less visually enthralling than a flask full of nascent amino-acids, however exciting its implications. But it was of laboratory shots of this kind, symmetrically interspersed with explanatory face-to-face monologues from such exobiological eminences as Leslie Orgel and Carl Sagan, that the film was principally composed.

The aim was to cover what can be guessed about the origin of life on Earth from the geological record and from attempts to reproduce the first chemical steps in the laboratory, as well as the current best guesses on the possibility of life elsewhere. The personnel in the field seemed fairly represented and the main ideas and experiments came over without conspicuous error or confusion.

But the film as a whole (with the possible exception of a somewhat gratuitous excerpt from Disney's "Fantasia") was visually dull, and the script

did little to compensate.

As messages in the media go, the health series planned for the Autumn by Children's Television Workshop, the makers of "Sesame Street", looks like making better television. They have, of course, the advantage of being able to recruit the talents of professional entertainers: warnings about hypertension are more arresting in the black-treacle tones of a first-rate blues singer than in the reedy ones of a medical expert.

Hypertension, in fact, has been singled out as one of the most important health hazards to US citizens, not least because it is prevalent in the black community. The other great 'national epidemic' is obesity, which, according to CTW, affects 60% of American men and 40% of American women. Hence a skit entitled "Fatman", featuring the Fatmobile and a villain called the Nibbler. The humour is unsophisticated, but then so presumably is most of the audience. More important, this public-spirited assault on some of the nation's great health problems looks like being eminently watchable.

matters arising

Small membrane-labels do not unambiguously reveal membrane 'sidedness'

SIR—Reaction of intact erythrocytes with certain small, radioactive or fluorescent organic anions labels fewer membrane proteins than similar treatment of erythrocyte ghosts. Several membrane biologists claim that this differential labelling derives solely from 'sidedness' of the membrane; they assume that ghost isolation does not change the orientation and/or intrinsic reactivity of membrane proteins.

The compounds tested however, [stilbene-4-acetamido, 4'-acetamido, 4'-thiocyano disulphonate^{1,2} (SITS); ³⁵S-diazobenzene sulphonate (DABS)^{3,4}; ³⁵S-formyl methionyl sulphone methyl phosphate (FMSMP)^{5,6} and trinitrobenzene sulphonate⁷⁻⁹], also react with the intracellular protein haemoglobin (Hb), indi-

cating that the selective labelling of membrane proteins in the case of erythrocytes cannot be simply ascribed to label exclusion. Also, dimethylaminonaphthalene-5-sulphonyl chloride (DANSCL) permeates erythrocyte membranes, combines with Hb (ref. 10), but, in intact cells, reacts only with the few membrane proteins also labelled by DABS, FMSMP and TNBS, while acetic anhydride (fully permeant reagent), labels membrane proteins equivalently in cells and ghosts¹¹; different reactivities of membrane proteins in intact erythrocytes have also been established for TNBS and picryl chloride^{8,9}.

Bretscher¹² attacks the caution^{10,11} that the differential labelling of erythrocytes and erythrocyte ghosts might reflect more than native 'sidedness'. Although the ambiguities in the use of small labels are listed¹⁰, Bretscher addresses only labelling studies with DANSCL and acetic anhydride. He ar-

gues that protons do not permeate membranes, that intracellular pH lies well below buffer pH, that the cytoplasmic membrane face thus bears only protonated NH₂-groups, which will not react with DANSCL or acetic anhydride, and that pH drops further during labelling.

Bretscher errs in his assessment of H⁺ distribution across the erythrocyte membrane and misquotes¹³⁻¹⁵. Indeed, it is established that H⁺ freely permeates erythrocyte membranes and that the transmembrane H⁺ distribution follows thermodynamic (Gibbs-Donnan) equilibrium. Intracellular pH, computed according to the Gibbs-Donnan relationship, accurately fits experimental measurements¹⁸. From this and the haemoglobin acid-base titration¹⁹, the intracellular pH for the cells in 155 mM sucrose, 52 mM Na₂HPO₄, titrated to pH 9.0 by 77 mM NaH₂PO₄ (ref. 10), approximates 8.4 and not 7.2 as implied¹². With amino

pKs near 9.5, and internal pH 8.4 this leaves many amino groups unprotonated. Dansylation proceeds even at pH 7.5 (ref. 20) well below the pH used before¹⁰. Poor dansylation at pH < 7, derives from hydrolysis DANSCL hydrolysis in aqueous solvents independent of H⁺ between pH 6.9 and 9.5 (ref. 21), and is reduced¹⁰ by use of high concentrations (2.5 mM) of DANSCL in a micellar vehicle. As H⁺ permeates erythrocyte membranes, transmembrane pH, after reaction, will still follow thermodynamic equilibrium. Even if the membrane were H⁺ impermeable, buffering by Hb (ref. 19), would keep the pH change, due to reaction of 5×10^8 sites per cell (ref. 10), to ~ 0.3 pH.

Thus, since SITS, DABS, FMSMP and DANSCL have access to and react in the cytoplasmic space of erythrocytes, these reagents may not report membrane 'sidedness' ambiguously.

Internal structure of Venus

SIR,—Bullen's recent reply¹ on this subject calls for further comment as it involves a number of misconceptions if not outright errors, and also some incorrect statements of fact. Only two main points will be dealt with here.

First, as a general theoretical consideration: with the mass M of Venus as datum, the only property known at present to be accounted for is the solid radius R_v as now determined by radar. If xM , yM , zM , and $(1-x-y-z)M$ are the proportions of mass in the inner core, outer core, mantle, and outermost shell, assuming four zones by analogy with the Earth, where x , y , z are all ≥ 0 , and $x+y+z < 1$ essentially, then with known pressure-density relation for each zone, the radius of the planet will in principle be some function $R(x, y, z) = R_v$. This can be regarded as the equation of a surface, in the positive octant of three-dimensional rectangular space, giving a double infinity of solutions each of which will be a possible model with correct R_v . It seems from Bullen's later full account² that the mantle and outer shell have been regarded as a single zone, so that in the present notation it would have mass $(1-x-y)M$, and instead of a surface there would be a curve $R(x, y) = R_v$ in two dimensions, giving a linear series of models with correct radius. It is not made clear how Bullen has overcome these mathematical considerations to derive a unique model. But in any event the step of regarding the mantle and outer-shell as one zone has been shown by the writer³ to affect the calculated radius of the Earth by an amount of order 100 km, and for Venus with its only slightly smaller mass, 0.815 M (Earth), the effect will not be very much less. Thus an error in radius of 50 km or more must be involved by this step, and the claim that the stated result for Venus fits the radius "extremely well" can only mean that the core values, which are highly sensitive to changes in radius, must be hugely incorrect to compensate for the oversimplification introduced for the mantle. Thus the alleged fit and identification with Fe_2O can be no more than a simulacrum, as is obvious anyway, since only the elastic constants and uncompressed densities of the materials can enter the determination of the radius.

Second, a factual point arising from Bullen's statement that "no useful favourable test of Lyttleton's theory has emerged since it was promulgated some ten years ago". This is far from being the case:

(i) My calculations went much further than the mathematical discussion of Ramsey (who did not make use of seismic data) and showed that the initial core after collapse of the planet would have less than 60% of the present radius, and that with further growth of the core to the present size would occur contraction of the surface-radius by some 300 km (ref. 3), implying a reduction of surface area by over $50 \times 10^6 \text{ km}^2$, thereby offering for the first time an amount of contraction of the order demanded by geologists for many decades to account for the numerous established periods of mountain building during the age of the Earth.

(ii) The theory predicted that Mars would be found to have no dipole magnetic field⁴ in spite of the rotation being close to that of the Earth. This was duly verified in July 1965 by the Mariner IV magnetometer, when the absence of a field was widely greeted as most surprising. (It seems that Bullen remains unaware of either the prediction or the result, which by some is considered one of the most significant achievements of the space programme, not only from his present remark but from its getting no mention in his 1969 review⁵.)

(iii) The theory also predicted that no folded and thrust mountains would be found on Mars⁶, and this too has recently become established by the Mariner IX mission.

(iv) The theory also predicts the presence of folded and thrust mountains on Venus. Although radar measures already claim large-scale features of vertical extent as much as 7 km (ref. 7), I would not regard this prediction as yet thoroughly established.

This list of successes could be seen as constituting quite favourable tests of the phase-change hypothesis, besides considerably outnumbering those achieved in upwards of a century by the iron-core hypothesis of which there seems to be exactly none other than the iterative claim that if a sample of the core could be obtained it would prove to be iron, or now Fe_2O .

Oxygen solubility and Henry's law

SIR,—Maharajh and Walkley reported¹ that the solubility of oxygen in water is reduced when another gas is present. The reliability of their data has been questioned on theoretical grounds² and by comparison with previously published data³. Maharajh and Walkley reported, for instance, that in a mixture of equal proportions of oxygen and krypton the oxygen solubility was depressed to less than half of its normal value. This result, if true, would be of great interest in the field of radiation biology because there are anomalous results in the literature on the effect of rare gases on the 'oxygen enhancement ratio'. We have therefore checked Maharajh and Walkley's findings, and as our results contradict theirs, we describe here our experimental arrangements in some detail.

The apparatus finally found most satisfactory is illustrated in Fig. 1. It produces a gas mixture of known composition which is bubbled through water to produce a saturated solution. A Hersch cell⁴ and associated sampling devices are used to measure the oxygen content of the saturated solution. The pressure vessel was evacuated and then filled to a known pressure with one component of the gas mixture. The second component was added to give a total pressure corresponding to the desired mixture. The mixed gas was thoroughly stirred by a fan sliding on a central rod inside the pressure vessel and was then bubbled through triply distilled water in the glass apparatus (a) shown in Fig. 1. One arm of this glass assembly couples directly into the Hersch cell through a stopcock. A sample of the water saturated with the gas mixture was withdrawn from the bubbling vessel by inserting the long needle of a Hamilton microsyringe through a flexible membrane, and then through the bore of a stopcock and into the solution. After the syringe had been flushed with the solution it was filled again and the needle was partially withdrawn and reinserted into the Hersch cell arm without the risk of any contaminating gas entering with it. A sample of 10 μ l was injected into the Hersch cell and the electric charge recorded in 3 min was measured. The Hersch cell was calibrated for oxygen sensitivity by alternating the test sam-

Fig. 1

Fig. 2

ples with a series of similar samples drawn from a solution saturated with pure O₂, which was contained in the second bulb of a in Fig. 1. The experiments therefore gave a direct comparison between the amount of O₂ dissolved in the mixed solution, and that dissolved in a solution equilibrated with pure O₂.

Figure 2 shows all our results for different proportions of oxygen with several different companion gases, in relation to the straight line expected from Henry's Law. At the 50% level (equal partial pressures of oxygen and the companion gas) where Maharajh and Walkley reported 60% depression of oxygen solubility in the presence of krypton, 34% with helium and 26% with nitrogen, we found no significant departures from Henry's Law. At small partial pressures of oxygen where the accuracy of measurement in our system is lower, some points lie slightly below the line, but these deviations are probably not significant. To increase the accuracy by an order of magnitude would involve considerable expense and time, which in view of the absence of anomalies does not seem justified.

CS₂ and the natural sulphur cycle

SIR,—The discovery of the ubiquitous distribution of dimethyl sulphide (DMS) led to the suggestion that this compound might constitute a volatile component of the natural sulphur cycle, serving to transfer sulphur from the sea to the land¹. I report now that in addition to

DMS another sulphur compound, CS₂, is widely distributed in coastal and ocean waters.

The presence of CS₂ was revealed during routine analyses of seawater for volatile halocarbons. Analysis was by gas chromatography with an electron capture detector. An unknown peak was almost always present at a retention time suggesting a substance with a boiling point of approximately 45° C. This is the boiling point of CS₂. Other physical properties of the unknown compound were also similar to those of CS₂: the retention volume on two different columns, Henry's Law coefficient for distribution between air and water, and the rate constants for reactions with diethylamine and with gaseous electrons.

There was a search for the presence of CS₂ in the waters off the Beara Peninsula western Ireland, in July 1973. It was present in every sampled locality but the highest concentrations were in relatively stagnant bays and the lowest were where the tip of the peninsula projected into the Atlantic Ocean. None of the species of algae examined were found to be emitting CS₂ but the concentration in anaerobic mud at the sea-floor was very much higher than that in the sea above.

TABLE 1 CS₂ in seawater

Origin	Concentration (g ml ⁻¹)	No. of observations
Atlantic off Ireland	7.8×10^{-13} (4.4)*	8
Stagnant bay water	5.4×10^{-13} (3.7)	12
Mud at sea bottom	2.95×10^{-11} (1.66)	5
Open Atlantic, (50°N 65°S)	5.2×10^{-13} (1.44)	35

* Figure in parentheses are standard deviations.

Analyses of seawater during the voyage of the RRS Shackleton from the United Kingdom to Antarctica and in 1971–72 show a peak with the same retention volume as that of CS₂. Although these historical data were not subjected to the same identification procedures as the data from the Beara Peninsula, it seems probable that the unknown peak was CS₂, and the results are listed together with those of the local analyses in Table 1.

The open ocean concentrations of CS₂ and DMS are respectively 5×10^{-13} and 1.2×10^{-11} g ml⁻¹. Calculations of the rate of transfer of these compounds from the sea to the air suggest that at such concentrations neither compound is a significant source of sulphur in the atmospheric part of the natural cycle (P. S. Liss, personal communication, and ref. 2). For CS₂ this conclusion is prob-

ably correct. Dimethyl sulphide, however, shows large variations in productivity: seawater in equilibrium with the alga *Polysiphonia fastigiata* contains 10⁵ times more DMS than the open ocean. Dimethyl sulphide therefore remains a likely compound of the natural atmospheric sulphur cycle. Carbon disulphide seems to originate under anaerobic conditions on the seafloor. It is stable for at least 10 d in seawater containing oxygen, and may therefore participate in the transfer of sulphur from the seafloor back to the surface waters.

Watson on pterodactyls

SIR,—I wish to draw your attention to a matter concerning the obituary of D. M. S. Watson¹.

It is mentioned that Watson was a very good lecturer and that "another fine performance was his lecture on pterodactyls, which he gave on several occasions but never published".

I and my colleague (Dr George Whitfield) have been working on pterodactyls for some years. Last autumn a batch of Watson's unpublished work came to light in the archives of the University of Cambridge. We examined the notes, which included the transcript of Watson's famous lecture on pterodactyls among other material. Whitfield and I had just had our paper on the Biomechanics of *Pteranodon* accepted by *Trans. R. Soc.* and were able to prepare Watson's material (including his lecture, word for word) and asked to have it included at the end of our monograph in a separate section. The Royal Society agreed to do so. The paper will be out in the next few months. We felt this would be a tribute to him and would preserve the lecture for the many vertebrate palaeontologists who had told us they had known of Watson's work on pterodactyls, and wished he had published it.

Lessons from Ethiopia

WE publish in this issue a report by an Oxfam-sponsored team on what can be learnt from the Ethiopian drought of last year. This is very much a first-hand report. Mr Mason and colleagues were in the area for much of the critical time last autumn when relief efforts, including their own, were turning the tide of fatalities. They are too modest about the success of the high energy food devised at Cambridge which undoubtedly brought many children back to health from the verge of death, but the greater achievement of this group and of many other devoted workers will come if their clearly spelt out recommendations are taken seriously and acted upon. It is at least highly encouraging that they report that a framework for relief can be based on established principles. An exotic or technologically complex solution is the last thing needed.

What is the prospect for 1974? Ethiopia has two harvests the first of which comes after the light spring rains. The failure of these last year led to the crisis; this year they seem to be much better in general, although the lack of seed and oxen will ensure that the harvest is small. In addition some first results from longer term aid will soon begin to prove their worth—road building and irrigation projects have made some progress. Nevertheless there are some fearfully large problems remaining. Perhaps the greatest of these is information flow.

Everybody one speaks to about Ethiopia (and this is hardly just an Ethiopian problem, although it is particularly severe there) is concerned about the lack of data. This was epitomised recently by the conflict between a Norwegian missionary's report that the south of the country was then in distress and a BBC reporter's failure to find any such situation. It is clearly inadequate that the forays of individual journalists should form the basis on which the world is alerted, and the solution is not one which poses vast technical problems, although it may well pose political ones. The sort of monitoring that nutritionists would like to see, the sort of information that would give adequate meteorological coverage, the sort of human animal and crop statistics that would give early warning of danger are such that a trained village postmaster could provide in many countries. Of course, there are no such people as yet in Ethiopia, nor are there means of communication. But it is surely not beyond the wit of a country that runs its own airline and uses computers in government to devise a suitable permanent reporting scheme. Surely in this it would have the support of international relief agencies.

Another widely mentioned obstacle to long term progress is the problem of land use and tenure. Much of

Ethiopia's fertile land is heavily overfarmed, largely because it is parcelled up into uneconomically small units, many of which are rented out at extraordinarily high rents. Often more than 50% of the produce from this land goes in rents. The Emperor and his family, it is said, own nearly half the land in Ethiopia, and the Church a further quarter. Clearly no rational approach towards self help can ignore this source of much harm. This is one of the issues behind recent political agitations in Addis Ababa and it is difficult to see it going away spontaneously. It is to be hoped that foreign aid-giving bodies with political clout will continue to raise this matter whenever future aid is being discussed.

And what lessons are there for the aid-giving bodies themselves? It has been alarming to learn that the disaster which only broke on the world in October 1973 was known as early as April 1973 to many people who were constrained by political sensitivities to respond in a low key way. It was by no means only those in the Ethiopian government who knew, although it seems that it was they who through ignorance or touchiness underplayed the expected scale of the disaster. Nevertheless the prospect of the tragedy was known in Britain in April and even without the starkness of Mr Dimpleby's television programme, it would surely have been possible to mobilise much financial and logistic support months earlier. One has great hopes that Mrs Judith Hart, the new British Minister for Overseas Development, will look very carefully at this question. She comes to the ministry with a good reputation and a burning conviction.

She might also with profit look carefully at the ways that other countries handle aid in the field. There are tricky problems of liaison and collaboration between government and private agencies. Some have spoken well of the German approach to the operation. It is clearly a field in which all can still learn much and, one hopes, can learn quickly and without worrying about loss of face and demarcation of duties.

100 years ago

THE Chair of Chemistry in the University of Glasgow is vacant. We hope the Home Secretary in filling up the vacancy will, in the spirit which urged the late Mr. Langworthy to make the magnificent bequest above referred to, show by the appointment he makes the appreciation in which he holds original research. It is now high time that it should be distinctly understood that no man deserves to be appointed to a Chair of Science in any of our Universities unless he has shown that he has that knowledge of his subject which can only come from original investigation.

The wind of hydrogen and of change blew gentle, clean and persistent at Miami...

"There was the sniff in the air of American technology on the move; much more will be heard of hydrogen before long." Professor R. W. Cahn, of the School of Applied Sciences, University of Sussex, gives his impressions of a recent conference on the 'hydrogen economy' held in Miami.

POLITICIANS and oil sheiks alike think of fuels as means of generating energy: another way of regarding them is as a means of storing energy. This approach was very much to the fore in the world's first conference on the 'hydrogen economy', organised last month by the University of Miami, with the backing of the National Science Foundation, amid the lush pleasures of the Playboy Plaza at Miami Beach. The international meeting was attended by over 700 participants, more than four times the number expected even by the buoyant organisers. Those attending were divided between the aficionados—and one of the opening speakers truly presented the adherents of the hydrogen economy as members of a quasireligious cult—and a large number of mild sceptics who were sufficiently intrigued to want to see how seriously the topic should be taken. The most popular question while sipping drinks among the bunny girls was: "And why are you here?"

Hydrogen is not a natural fuel on earth. It must first be made, most conveniently from water, and then turned back to water, generating heat (or electricity directly in a fuel cell). Since neither generation nor combustion is perfectly efficient, the cycle $H_2O \rightarrow H_2 \rightarrow H_2O$ only makes sense from three aspects: it offers a compact means of storing and transporting energy which is not conveniently used at the site and time of liberation; it provides a possibility of creating a transport-fuel with very high energy content per unit mass; and it provides one possible substitute to pass through the insatiable natural gas pipelines of North America.

Nearly 100 papers (available in a preprint volume from the School of Continuing Studies at the University of Miami) were presented broadly on the following themes: generation of hydrogen by means of nuclear, solar or geothermal energy, and specifically by electrolysis or thermochemical cycles with catalysts, or by steam reforming of carboniferous fuels; storage of hydrogen as liquid or, more especially, in thermally decomposable hydrides; transport of hydrogen through pipelines, including problems of embrittle-

Hydrogen is not a natural fuel on earth. It must first be made, most conveniently from water, generating heat, or electricity directly in a fuel cell.

ment by hydrogen; hydrogen as a fuel for cars and aircraft; the relative cost of hydrogen and other fuels, particularly methane, for various uses. Indeed, the conference was notable for the scrupulous care devoted to the economics of the various patterns of hydrogen production and use. The many attempts at costing covered a moderately wide spectrum, and one author's assumption was on occasion disproved by another author's technical innovation. Thus, one

of the numerous papers on thermochemical cycles, by R. I. Chao (University of Puerto Rico) and K. E. Cox (University of New Mexico), concluded that "thermo-chemical hydrogen via a series of closed chemical cycles and nuclear heat would cost \$1.50–2.35 per million BTU, whereas hydrogen from electrolysis/nuclear power would cost \$4.60–6.28 per million BTU" (compared with present jet fuel costs of \$1.7 per million BTU). But Chao and Cox assumed electrolysis capital costs at \$200 per kW, whereas L. J. Nuttall, A. I. Fickett and W. A. Titterton of the General Electric Company (GE), in their very impressive paper on hydrogen generation by electrolysis with solid polymer electrolyte

Hydrogen fuelled cars seemed fairly promising, but such cars would probably require a huge discontinuous change in distribution which could scarcely come by easy stages.

estimated capital costs which might be as low as \$60 per kW and overall hydrogen costs in the range of \$2–3 per million BTU (excluding liquefaction costs), which is distinctly interesting in the medium term. The GE paper was a good example of high technology transfer, since it described a thoroughly engineered process originally designed to make tonnage oxygen for the space programme, with hydrogen going to waste; this could easily be turned on its head. The GE technique effectively separates the two gases; permits extremely high current densities and, very important, gets by with exceptionally low loadings of noble metal catalyst. Ordinary commercial electrolyzers cannot afford to use catalyst and thus have to operate very inefficiently.

The numerous papers on thermochemical cycles left a overall impression of a technologically very difficult method dependent on extremely efficient recovery of catalyst and with many uncertainties as to overall efficiency of energy conversion. It is also remarkably difficult to decide an optimum series of chemical cycles for investigation: even a computer-aided search of possible cycles, by J. L. Russe and J. T. Porter of the General Atomic Company, gave conclusions which are hard to evaluate. One listener was left with the impression that electrolysis scores on points over thermochemical cycles, until the end of the century at least. This view was not weakened by a very interesting paper by J. B. O'Sullivan and others of the United States Army, who described a detailed and, hitherto unpublicised feasibility study of a mobile hydrogen generator for field use, centred on a thermochemical cycle. The full details of this are to appear in the final proceedings of the conference, to be published by Plenum Press.

Opinions were violently divided on hydrogen as a fuel for internal combustion engines. E. M. Dickson and colleagues of the Stamford Research Institute presented a closely argued critique, with pessimistic conclusions, of the use of hydrogen to fuel 'personal vehicles'. An enthusiast, R. E. Billing of the Billings Energy Research Corporation (many small companies were represented) however described in optimistic detail his own experience of operating a fleet of hydrogen fuelled motor-caravans, and he also claimed considerable

operating data of a converted passenger car working interchangeably with hydride or cryogenic storage.

Papers dealing specifically with hydrogen storage in cars were particularly interesting. Several discussed the detailed engineering design of hydride storage beds, mainly with reference to $\text{FeTiH}_{1.6}$ and MgH_2 . The first of these is heavy but decomposes at low temperatures; the second is light but needs to be heated to over 600°C . Billings explained how an optimum (i.e. lightest feasible) combination of the two hydrides could be used, with as much MgH_2 as could be sufficiently heated by the exhaust gases of the engine, while hydrogen was liberated from the other hydride by means of the engine-cooling fluid. Considerable and sophisticated attention was paid to the engineering design of hydride beds for fastest possible charging and discharging for instance by G. J. Powers and D. C. Cummings of MIT. The kinetics of hydride formation or decomposition may be limited either by heat flow or hydrogen diffusion; the consensus appears to be that in the best designs, heat flow is limiting. Complete charging of a hydride bed in five minutes was claimed by one speaker; this is unlikely to be bettered.

Overall, the technology of hydrogen-fuelled motor cars seemed fairly promising; as several speakers pointed out, however, hydrogen-fuelled cars (like hydrogen as substitute natural gas) would probably require a huge discontinuous change in distribution over the whole of a large area all at once; it could scarcely come by easy stages.

Methanol, which can be made by a hydrogen route, received attention as a possible automotive fuel. In an impressive paper modified by some last-minute findings, T. B. Reed and R. M. Lerner of MIT dealt with the potential for progressive lacing of petrol with synthetic methanol, as methanol gradually becomes cheaper relative to oil. The prospects are promising, according to this work, that increased methanol content will so improve anti-knock properties that the lead content can be considerably lowered or perhaps even eliminated. The conflict of all-or-nothing versus progressive introduction of new fuels was one aspect of the 'social' approach to the hydrogen economy which several speakers essayed. Dickson's paper from Stanford was outstanding in this connection. He analysed the magnitude of the impact of various changes inseparable from a hydrogen-fuelled car economy and also examined which groups of people (drivers, mechanics, fuel dispensers, fuel distributors, fuel manufacturers) were affected. His histori-

Aviation will be the first major user of hydrogen, well before the century is out. The larger the aircraft and the greater the range, the greater is the economic advantage of using liquid hydrogen.

cal parallels—for instance, the disincentive to the spread of diesel-fuelled passenger cars which he identified with the mild inconvenience of locating supplies of diesel fuel—lead him to argue strongly that while quite major changes in engine design, such as the Wankel engine, can be quite readily accommodated, relatively modest changes in nature of the fuel, and especially of fuel distribution, will constitute major blockages.

One advantage of the kind of analysis offered by Dickson is that it can alert technologists to needs that otherwise might be underestimated or even ignored. If it is accepted that the introduction of a hydrogen-only car would come up against particularly intractable socio-political resistances, then there is a strong incentive to develop an engine that can run on either of two alternative fuels—such as the hydrogen/methanol engine described at the conference by

R. R. Adt of Greenwell and M. P. Swain of the University of Miami. Technology and economics are but two sides of a triangle, of which politics forms the base.

The long paper by T. C. Cody of West Virginia University on the hydrogen economy and (American) law was particularly thought provoking. Cody foreshadows in-

If it is accepted that the introduction of a hydrogen-only car would come up against intractable socio-political resistances, there is a strong incentive to develop an engine that can run on either of two alternative fuels.

creasing "federal preemption" over the states in safety and environmental legislation and a progressive sharpening of legal limitations on energy use: eventually he foresees a law of allocation to replace the present 'crazy-quilt of contradictions, cross-purposes, omissions, overlap and duplication.'

On hydrogen for aviation, opinions were also divided. R. A. Lessard, an economist of the United Aircraft Research laboratories, in a separately circulated paper, was sceptical on purely economic grounds, whereas P. F. Korycinski and D. B. Snow of NASA were optimistic on the basis of a detailed technical analysis. The larger the aircraft and the greater the range, the greater is the economic advantage of using liquid hydrogen. One listener at least was left with the clear impression that aviation will be the first major user of hydrogen, well before the century is out. This view was shared by a severe critic of the hydrogen economy, P. N. Ross, a vice-president of Westinghouse, who was utterly convinced that nuclear electricity, distributed as such, would indefinitely defeat the use of hydrogen—except for aircraft.

There is no space to do justice to the group of papers on solar and geothermal energy (the latter seems particularly promising in an American context). The conference showed very clearly its recognition that hydrogen is merely a means of storing energy, not creating it. Some new, cheap solar cells were developed and evaluated, the engineering aspects of a mile-square servo-controlled mirror array and boiler tower were analysed, there was much to do about large floating platforms making use of thermal gradients in the oceans (a form of indirect solar energy) and wind power came in for some detailed analysis, not least in connection with a self-contained domestic system using only established technology, including energy storage by electrolysis and later use of the hydrogen. This intriguing study was by L. W. Zelby of the University of Oklahoma, where the wind is gentle but persistent.

Indeed, the wind of hydrogen and of change blew gentle, clean and persistent at Miami. The fact that hydrogen is almost pollution-free was much commented on (but see *Nature* for March 29, page 458); the name of the Environmental Protection Agency was much mooted and an International Association for Clean Energy was founded at the conference. There was the sniff in the air of American technology on the move; much more will be heard of hydrogen before long.

Fuel prices and the energy crisis

Fuel	Price before the energy crisis (\$ per million BTU)	Estimated 1974 price
Natural gas	0.25	0.70
Fuel oil	0.32	1.80
Coal	0.20	0.58

international news

EVERY year 7,000 people in Britain die from kidney disease. Five thousand of these die simply because a cure for the chronic form of the disease has not yet been found; the remaining 2,000 fall into the category that are likely to respond to a kidney machine or to a transplant, but they die because there are not enough machines or cadaver (donor) kidneys to go round. In the short term, a rapid turnover to transplantation permits the acceptance of more patients into dialysis units and so an immediate and urgent need is for many more cadaver kidneys.

Twenty-three transplant units have been set up in the United Kingdom since the Medical Research Council advised the Department of Health and Social Security in 1967 that renal transplantation had 'passed beyond the research stage'. Surgeons now perform more than 500 transplants between them every year; the survival rate has continued to climb steadily and kidneys have proved themselves the most suitable of all transplanted organs. But the demand for kidneys far exceeds the supply, and it is a lack of understanding and cooperation among doctors themselves that is largely to blame.

"Organ donation" said a report issued by the Royal College of Physicians (RCP) in 1972 "involves the doctors caring for the patient in a considerable amount of extra work and trouble. They must talk to the relatives, consult the coroner and make numerous telephone calls. Most of these patients are not now considered as organ donors because the question is never raised. Yet this negative attitude is the major limiting factor in the expansion of a renal transplant service . . . Most important of all," the report concludes, "is for there to be more cooperation within the medical profession so that the donor organs are not wasted."

Some London hospitals were already engaged in a kidney-sharing programme and as a result of their example and the RCP's report, the Department of Health set up in 1972 the National Organ Matching Service based at the Southmead Hospital in Bristol. The names of patients waiting for kidneys are kept on a computer and when donor kidneys become available the most suitable recipient is selected. The following year, the Department issued 2,000,000 donor cards, which although never intended as legal documents were designed to enhance the public's aware-

ness of the kidney problem. But neither the donor cards nor the matching service has provided the results everyone was hoping for.

There were no more kidneys available last year than in 1972; and surgeons are particularly disappointed at the comparatively small number of matches effected by the Bristol centre. But there

Transplants: the failing machinery

Robin Laurance

is special concern about the reluctance of some hospitals to share out the kidneys which are not suitable for their own patients. Last year, for instance, the Hammersmith Hospital received 38 kidneys from the pool but contributed only six. St Mary's Hospital took 31 and contributed 8; Queen Elizabeth's Hospital in Birmingham, on the other hand, received 38 and contributed 74.

In addition to an apparent lack of cooperation between the surgeons themselves, there is an even greater gap between the surgeons and the rest of the profession. Mr Anthony Barnes (the surgeon involved in a recent controversial transplant operation at Birmingham, said to have been started before the donor was dead) says the main problem is ignorance and that the majority of doctors simply are not aware that transplants are such a successful treatment for kidney failure. His

own success rate is very high and yet a consultant from another department in his own hospital walked through his ward recently and asked whether he had anyone still alive after a transplant. Mr Barnes spends every spare minute visiting hospitals in his area reminding doctors and surgeons about kidneys. But there are still a number of hospitals from which he has never even had the offer of a kidney.

A member of another kidney team recently accused doctors of being reluctant to ask relatives for permission to take kidneys from newly dead patients. Some doctors, he said, take it as a personal failure when a patient dies, but they should appreciate that a kidney could save another life. "I know it seems callous," he said, "but we have to educate our accident colleagues that it is necessary to act quickly when a suitable patient dies."

Michael Bewick, who transplants kidneys at Guy's Hospital, London, says it is "quite appalling" to have to ask relatives for permission to retrieve kidneys soon after bereavement. He says the Department of Health should introduce an 'opting in' system where everyone would be formally asked to consider becoming a potential donor. The tissue details of all those who agreed would be kept on the computer at the Organ Matching Centre and when anyone died suddenly or was suffering from a terminal condition, the doctor would simply check if his patient was on the computer's list.

Roy Calne, Professor of Surgery at Cambridge, favours an 'opting out' system whereby everyone becomes a potential donor unless he registers his dissent. Professor Calne says a change in the law and more collaboration within the profession are the best ways of meeting the ever increasing demand for kidneys. "But", he says, "I doubt whether there will be a significant improvement until the public puts pressure on both the government and the medical profession. And that won't happen until the results of kidney transplantation are well enough known."

The Department of Health and Social Security is unlikely to introduce either an 'opting in' or an 'opting out' system in the near future, although Dr. David Owen, Under Secretary of State for Health, said recently in a Commons written reply that such a scheme was under consideration. The department is, however, launching a publicity cam-

paign with 30,000 posters to be sent to hospitals and doctors' surgeries reminding people that when they die, their kidneys could save other people's lives. But without a change in the law, any positive response will only cause frustration all round.

So the problem comes back to the doctors themselves, who have to make the most of the kidneys that come their way. One of the headaches here is defining the moment of death in the donor—a problem that has become even more difficult in recent months with the increasing use of ventilators. For a successful transplant, a kidney must be extracted within an hour of death and where the patient is being kept 'alive' artificially by ventilation the doctor (and in transplant cases, two doctors are required to certify death) must decide when the brain has died and when the ventilator has passed the point at which it will invoke any involuntary response in the patient.

Anthony Barnes maintains that many doctors are still only learning when to turn the ventilator off. Some, he says, do an injustice to relatives by allowing their patients to rot with a brain that is never going to work again. "And the kidneys become rotten too," he says, "and that's an awful waste." And to rub in the dilemma facing doctors, the coroner at the Birmingham inquest involving Mr Barnes, told the jury that

A patient receives a transplant kidney at Guy's Hospital, London

there was "considerable dissension among pathologists he had questioned about when a person was dead".

Doctors abroad involved in kidney transplants already have fewer problems. In France, and in some parts of the United States, brain death is accepted as a clear index of death, which means that much fresher kidneys are available from donors who are still breathing. (It also, of course, means

that many patients are spared lives as cabbages.) The Americans also have the Uniform Anatomical Gift Act which has made donor cards legal documents.

And in Scandinavia the law says a doctor can take what he likes from a corpse, with no questions asked. Clearly, legislation along these lines would make life easier for transplant surgeons working in Britain.

THE pay of government scientists in Britain will continue to be determined by reference to that of scientists in industry rather than by comparisons with other branches of the Civil Service if the recommendations of the Pay Board on Science Group pay are accepted as policy.

About 16,000 members of the group are affected by the report of the board, which appeared after a protracted dispute over the criteria for determining their salaries. The scientists, represented by the Institution of Professional Civil Servants (IPCS), were loth to accept a pay research exercise referring to the rates of scientists in industry because, it was argued, the government was such a large scale employer that industrial rates were themselves determined by the level of pay in the public sector, and so any comparison would be prey to an illogical circularity.

The report says, however, that the process of pay research is not invalidated by these special circumstances, and that they can be taken into account, either by the Pay Research Unit (PRU) in making comparisons or where this is not possible, by the parties involved in negotiation.

The IPCS had pointed out in evidence to the board that scientists

Pay Board reports on scientists

had not had a substantive pay review since January 1971, when there was a measure of parity between their rates and those of comparable grades in the Civil Service Administration Group. By January this year the scientists had fallen behind, at the scale maxima, by as much as £880 at Principal Scientific Officer (PSO) level, and £731 at Higher Scientific Officer level.

According to the IPCS new rates should have been determined, according to a principle of the Priestley Commission, by internal relativities, using the Professional and Technology Group as a comparison, rather than the Administration Group, as in the past. But the only point at which the Pay Board leaned towards internal relativities was in its suggestion that PSO rates should at both ends of the scale (currently £3,715 and £4,895) be no more than 5% away from the rates for their counterparts in the administrative grades. As a corollary, the report recommends that the maximum of the Senior Scientific Officer scale (now £3,895) should be adjusted

if pay research does not produce an appropriate differential with the minimum of the PSO scale.

Both these adjustments would take into account what the report calls the "unquantifiable" factors of individual merit and the differing career pattern of government scientists, who tend to go on working in research and development long after the age at which their industrial counterparts have moved on to greener pastures. About 5,500 scientists would be affected by this suggestion.

The remaining 10,500 members of the Science Group will have to be content with pay research, although there is a recommendation that procedures for the exercise should be reviewed jointly by the scientists, the Civil Service Department and the PRU.

The IPCS said it was "severely disappointed" with these formal recommendations, which would take a long time to implement (January 1976 has been suggested as the earliest date by which the exercise could even get under way). But the union adds that, given goodwill on the part of the government, there is no reason why an agreement should not be reached and it has entered an interim claim, based again on internal relativities.

Berkeley's line on PWRs

Eleanor Lawrence

THE Nuclear Laboratories at Berkeley in Gloucestershire provide the Central Electricity Generating Board (CEGB) with nuclear research facilities and expertise without parallel in any electricity utility in the western world according to CEGB Board Member Mr Donald Clark. At present, with the CEGB's controversial proposal to buy American-designed pressurised water reactors (PWRs) very much in the air, evaluating and verifying work on the safety of these reactors is one of Berkeley's most pressing problems.

According to Dr Bryan Edmondson, the director, very recent work by Westinghouse on the PWR pressure vessels indicates that there may be less danger than feared of the catastrophic crack propagation emphasised by opponents of PWRs. At the temperatures at which the reactors operate, defects in the steel pressure vessels would probably propagate by plastic deformation and not by sudden crack propagation. In a half-size model with 6-inch walls (compared with 12-15-inch walls in the full-size vessel) Westinghouse tests have shown that this does in fact lead to a 'leak-before-break' situation.

Dr Edmondson emphasises that this, although comforting, is not the sort of information on which the safety case for the reactor could be based. Quality tests during manufacture, overpressure testing before service and regular in-service inspections are the best lines of defence. Also, as the vessels need not be fully pressurised until a temperature of 300° C, they can be carefully controlled during the heating up process through temperatures at which the danger of catastrophic crack propagation is greatest. The pressure vessels are also more accessible to repair and inspection than the innards of the gas-cooled reactors and, as technology has been developed to deal with crack detection in those circumstances, Dr Edmondson is hopeful that it will not prove too big a problem with PWRs.

Commenting on the memorandum sent to the Select Committee on Science and Technology by Sir Alan Cottrell, highlighting the problems of pressure vessel safety, Dr Edmondson says that he could not disagree with Sir Alan and had been giving similar advice to the Board, but that the results of the Westinghouse tests had not been available then.

Berkeley is also evaluating the American calculations on what would happen to the pressure vessel in the case of a loss-of-coolant accident when it would be subjected to a shock of cold water.

The laboratories are now half-way through the stress analysis and so far have come up with the same reassuring answers as the Americans, whose calculations have been accepted in the safety case in the United States.

Dr Edmondson emphasises that because the PWR matter is so controversial much more evaluation and verification of already published results, which would normally be taken on trust, is having to be done. But he does not expect that the findings will differ drastically from previous work.

Russia's Mars probes

from our Soviet Correspondent

THE ANNOUNCEMENT of the partial failure of the latest Soviet Mars experiment—the probes Mars-4 to Mars-7—was one of the less auspicious features of the Jubilee General Meeting of the Academy of Sciences on March 5th 1974. Already it was known that the breaking motors of Mars-4 had failed to operate so that it achieved only a close by-pass at 2,200 km. Nevertheless some good photographs had been transmitted from Mars-4, and Mars-5 was satisfactorily in orbit investigating the planet, its atmosphere and ambient space and two further probes were still on their way.

However, Mars-6 and -7, which reached the vicinity of the planet on March 12th and 9th respectively were unable to retrieve the hopes of the programme. Although the official Tass announcement called their flight "an important step in the investigation of Mars", the news was depressing. The two probes had carried descent capsules, which would investigate the surface and relay data to the orbiting section for re-transmission. There had even been speculation (evoked by a Pravda article on future plans for planetary research) that one of them might be carrying a roving "Marsokhod". However, radio contact with the descent stage of Mars-6 was lost when it had reached "the immediate vicinity of the surface", and a failure in the on-board systems of the descent stage of Mars-7 after separation resulted in a fly-by at 1,300 km. The "orbital" stages of these two probes apparently failed to enter aero-centric orbit, since they are reported to be "investigating the physical characteristics of space" from helio-centric orbits. So the overall design of the experiment, with four orbital stations monitoring the same data from different altitudes together with two surface probes (the previous programme used only two such stations and one surface probe), has been reduced to a single orbital station and a number of

fly-by photos, valuable though these are.

The claims in the Soviet press that nevertheless valuable results have been obtained are not however merely an attempt to save face. Photometry readings, for example, have revealed a maximum precipitation of some 60 nm—a value several times greater than that recorded by similar instruments aboard Mars-3 in 1972, which, it is suggested may indicate a different rate of release of water vapour from the crust into the atmosphere in different regions of the planet. Traces of atmospheric ozone have been noted for the first time. The existence of the magnetic field of the planet (indicated by the data of Mars-2 and -3) has been confirmed, and readings have now been obtained for the magnetic field on the dark side of the planet.

Nevertheless, a sense of disappointment is apparent and a long article in Pravda, March 20th, on the engineering problems of designing planetary probes may well reflect not only a desire to restore public confidence but also some serious re-thinking by the planners of the "hardware" situation.

ELSE in Israel

Nechemia Meyers, Rehovot

EDITING and publishing a scientific journal is a very ordinary venture which anybody can do, and almost everybody does—at least, in the opinion of Mr Paul Nijhoff Asser, Secretary General of the International Group of Scientific, Technical and Medical Publishers. Mr Nijhoff Asser made this judgment at a recent meeting in Israel of a small but influential group of scientific communicators, the Executive Council of the European Association of Editors of Biological Periodicals (ELSE). He was commenting on a report from ELSE treasurer, Miriam Balaban, that 130,000 scientific journals are currently being produced and that the number is rising.

The European editors, who in the past have seemed anxious to demonstrate their independence of United States influences—preferring, for example, to issue their own manual of scientific writing and terminology—nevertheless invited an observer from their American counterpart organisation, the Conference of Biological Editors. Dr Karl Heumann, Executive Editor of the Federation of American Societies for Experimental Biology, took an active part in the discussions and suggested that editors should carefully consider whether to publish papers describing experiments in which the human participants were not aware of the risks they were taking.

Small though the meeting was, the Israelis present regarded it as another victory in their continuing struggle to establish their European credentials.

Academy exposes a sham

Colin Norman, Washington

FOR years now, spokesmen for the Nixon administration have been touting the line that federal research and development expenditure are gradually being focused on programmes which will benefit society and help solve "critical domestic problems" in the United States. Such sentiments reached their zenith two years ago, in March 1972, when President Nixon sent his first, and only, message to Congress on science and technology. His statement was replete with rhetoric about a new partnership which would be forged between government, industry and the universities, to help bring the fruits of technology to the people.

But a committee of the National Academy of Engineering (NAE), the most prestigious engineering organisation in the United States, published a report last week which came close to suggesting that most of President Nixon's science and technology message has turned out to be a complete sham.

The committee states that "with a few exceptions, the vast technology developed by federally funded programs since World War II has not resulted in widespread 'spin offs' of secondary or additional applications of practical products, processes, and services that have made an impact on the nation's economic growth, industrial productivity, employment gains and foreign trade".

The committee's general thesis is that technology developed with federal funds probably hasn't been exploited for the good of the people (or at least for the good of corporate profitability) because "a plethora of structural and institutional barriers exist in the federal government and the private economy to prevent the efficient and effective utilisation of this technology". Furthermore, since there has never been a comprehensive effort to search out technology which can be usefully exploited, it is difficult to recommend policies in such a vacuum of knowledge.

The NAE's findings and conclusions are shared by many observers of federal science policy, including a few key members of Congress. It was only just over a year ago, for example, that the Senate passed, by a huge majority, a bill sponsored by Senator Edward M. Kennedy which would have given the National Science Foundation a large budget to bring federal research and development to bear on such critical problems as urban renewal, health care delivery and transportation.

The bill died because it was never approved by the House of Representatives, but the sentiment lives on. Just

MERCURY as seen by the cameras of Mariner 10. Left, heavily cratered area reminiscent of the highlands of the Moon, including a bright rayed crater. Picture taken from about 400,000 km resolves craters 120 km or more in diameter. Below, closeup picture taken from a distance of 20,700 km about 30 min before closest approach. The clearly defined central crater (about 12 km across) is a relatively new feature.

last month, for example, the Senate Committee on Science and Astronautics held extensive hearings on a bill which would provide NASA with a large helping of money to promote civilian technology. The bill is not likely to get anywhere this year because, even if it is approved by the Senate, the House of Representatives has so far shown little interest in the measure and in any case congress is likely to be occupied later this year with impeachment fever.

But there continues to be considerable feeling on Capitol Hill that there is a lot of federal research and development which could be usefully exploited if only suitable arrangements could be worked out to accomplish the task.

The NAE committee, at least, has a few concrete recommendations for removing some of the barriers to innovation which have prevented private companies from turning federally produced technology into marketable products. For a start, it suggests that the federal government should spend \$1,000 million a year in helping to promote the utilisation of technology through a variety of incentives and government programmes.

The first task should be to conduct a survey of federal laboratories, to test "the assumption that there is a substantial amount of useful federally funded technology available for beneficial, widespread secondary application."

Assuming, as the committee does, that

the survey turns up positive results, federal agencies should set up explicit programmes with specific charters for embarking on technology utilisation projects, and they should be given funds earmarked in the agencies' budgets for that purpose. Certainly, some agencies, such as NASA, have already established such offices, but the NAE committee reckons that much more could be done. But the committee is quick to point out that its recommendations in no way "imply that the federal government should become a competitor to the private entrepreneur", for the idea is that once a technology has been developed, it would be adapted, produced and marketed by private industry.

In order to stimulate that end of the process, the committee suggests that the federal government should provide a variety of incentives such as risk assurance, exclusive licences and "imaginatively bold financing to users in the public and private sectors in order to accelerate the direct implementation or to stimulate financial institutions to provide greater investment in new technology".

If all that sounds familiar, it is. Such suggestions have been made by virtually every committee which has studied the federal government's role in exploiting research and development financed by the taxpayer for the good of the taxpayer. But so far, there's little sign that anybody is listening.

correspondence

Newton and Kepler

SIR,—I have only just read Dr J. W. Herivel's review in your journal (*Nature*, January 18, 163–164) of the recently published variorum edition of Newton's *Principia*. There I am fathered with I. B. Cohen's view—"originally put forward [in my article on 'Newton's early thoughts on planetary motion in'] *Br. J. Hist. Sci.* 2, 117–137 (1964)"—that Newton "apparently learnt of Kepler's law of areas in 1678 and at once was able to solve the problem of Keplerian planetary motion" (Herivel's italics). Quite bluntly, I have never said anything approximating to that, with or without its emphasis, there or anywhere else.

In my 1964 article I did, to be sure, publish my (then) novel finding that nowhere in his extant early papers "does Newton make any mention of Kepler's area law"—with the qualification in a footnote thereto (page 124) that in his "deep study at an early age of Wren's . . . tract [on Kepler's problem, as published by Wallis in his *De Cycloide*, 80 (1659)] . . . it is just possible his attention was caught by the fleeting reference [there] to the area law"—and then went on to observe (page 131, note 48) that Newton possessed in his personal library a "well-thumbed" copy of Nicolaus Mercator's *Institutiones Astronomicae* (1676) where, as I wrote, "correct enunciation" of the planetary law is given. That it is, as Herivel now says, "stretching credulity to suppose that Newton had not . . . deeply pondered on this extraordinary law before 1679 [sic]" may or may not be everyone's modern reaction; but such an undocumented opinion is certainly irrelevant when, as I did, one comes to examine the available historical evidence. I know nothing of Herivel's recent scholarly activity in this area but after my own nearly twenty years of continuous study of Newton's scientific papers (including many in private possession which are not generally accessible) I will reiterate that I have as yet found nothing which establishes in any way that Newton was, before 1676, aware of the law's verbal enunciation or begins to hint that he "deeply pondered" its meaning at any time before late 1679. If Herivel knows better than I, let him state his sources.

As for the portion of Herivel's quot-

ation which he italicises, this, whatever its truth, greatly traduces the hypothesis which I formulated in my 1964 paper. There I made Newton's "sudden" appreciation of the validity of the area law in 1679 dependent, not on his presumed ignorance of the law's statement up to that time, but on his recognition of its theoretical necessity in his proof of the elliptical orbits of the planets under the condition (as Hooke laid it down in their correspondence in the early winter of 1679–80) that their undeviated motion be uniform and in a straight line. Herivel knows this very well since, on the appearance of my article 10 years ago, he mounted a hasty and often ill-considered but full-blooded attack on it in *Br. J. Hist. Sci.* 2, 350–354 (1965), in the course of which he allowed my hypothesis to be "possible [but] very improbable". That unsupported judgement is evidently now to be sanctified by similarly ruling out

Brevity

CORRESPONDENCE stands more chance of being published if it does not exceed 350 words. The Editor reserves the right to abbreviate any item.

as "very improbable" a distortion of my original thesis which I have never held. May I ask Herivel to acknowledge as much and to retract his present aspersions?

D. T. WHITESIDE

Cambridge, UK

DR HERIVEL REPLIES: Dr Whiteside protests at my "fathering" on him the view of I. B. Cohen that Newton "apparently learnt of Kepler's law of areas in 1678 and at once was able to solve the problem of Kepler motion" (my italics). This view seems however, to have been suggested to Cohen by Whiteside's 1964 paper to which he refers immediately afterwards. This does not seem so improbable as it might otherwise appear from Whiteside's letter in the light of the following passage in his paper (page 128):

"We have said enough to justify our general contention that in the autumn of 1679 Newton was, if indeed he at all consciously then recognised its existence, still unwilling to allow Kepler's crucially important second (areal) law even an empirical place among the axioms of his astronomical thought."

I myself derived somewhat the same

impression as Cohen from a reading of Whiteside's paper. For in my "hasty and often ill-considered" paper of 1965 I said:

"to the various explanations already put forward, a new one has recently been added by D. T. Whiteside, namely, that Newton was prevented from solving the problem of Kepler motion before 1679 because up to that time he was either unfamiliar with, or had no confidence in, Kepler's second law of planetary motion".

As regards the second, italicised, part of Cohen's view, although I did not draw this conclusion myself I can quite understand Cohen's doing so. For if Whiteside's paper is interpreted as implying that Newton was unfamiliar with Kepler's second law up to the autumn of 1679, and if he required this law for his solution to the problem of Kepler motion in the following winter, then it does not seem unreasonable to conclude that it was his tardy acquaintance with this law which led to the solution of the problem.

In the light of Whiteside's letter I am quite happy to retract the phrase "This view originally put forward by D. T. Whiteside". But in fairness to I. B. Cohen, and for the sake of the historical record, I should want to replace it by the following: "this view was apparently suggested to I. B. Cohen from a reading of a paper by D. T. Whiteside".

As to the important question of whether or not Newton was consciously aware of the exact, areal form of Kepler's second law before the autumn of 1679, it seems to me that in the light of Dr Russell's findings the onus is on Whiteside to provide documentary evidence for a lack of familiarity on Newton's part. In the absence of this evidence I for one will continue to believe that Newton was perfectly well aware of the exact form of the law long before 1679, most probably from a reading of Kepler's *Epitome*. For if Dr Russell is correct in believing that this famous work of Kepler was "from about 1630–50 or beyond almost certainly the most widely read treatise on theoretical astronomy in Europe" (*Br. J. Hist. Sci.* 2, 20; 1964) then I find it very difficult to believe that it was not read by Newton. Documentary evidence is important, and without it history cannot be written, but its absence does not necessarily preclude the historian from drawing probable conclusions in other ways.

news and views

Should fossil hominids be reclassified?

RICHARD LEAKEY's report in this issue of *Nature* signifies the end of the sixth field season in the Lake Rudolf area. In those six seasons important new fossil material has appeared at a rate almost too fast for scientific interpretation if not intellectual assimilation. At present, it is possible to discern two important contributions of the East Rudolf work, although a greater time perspective may indeed add further dimensions and ramifications to present interpretations of the Rudolf material.

The first and most obvious contribution has been the enormous increase in the size of the fossil sample, not only of hominid material but also of other Primates and vertebrates. The work at Rudolf has so far yielded approximately 107 specimens of fossil hominid; by comparison, Olduvai Gorge, an area noted to be very productive of fossil material, has yielded only about 40 hominids in nearly as many years. A second important result of the Rudolf work has been a recognition of the necessity to examine closely some of the earlier concepts and interpretations of human evolution. Before the 1970s the widely accepted model of human evolution suggested a slow and orderly emergence of a more advanced evolutionary grade of man from a primitive basal stock. In this way, late Pliocene-early Pleistocene australopithecine populations were seen to develop slowly into middle Pleistocene populations, generally attributed to *Homo erectus*; in fact, the process may not have been so simple.

The fossil evidence of man at East Rudolf now demonstrates a very wide morphological variation. There is clearly a large, robust-type australopithecine as seen in the cranium KNM-ER 406, mandibles KNM-ER 729, 818, 1806 and other specimens. There is also evidence of a more lightly built and perhaps more advanced group seen in the crania KNM-ER 1470 and possibly 1590, mandibles KNM-ER 730, 820, femur KNM-ER 737 and others. Certain specimens, notably the cranium KNM-ER 1805 and the mandible KNM-ER 1482, have proved difficult to assign to any currently recognised group. An interesting aspect of the Rudolf material has been the apparent absence of the gracile form of australopithecine. This type is well known from sites in South Africa and from Olduvai Gorge and now Leakey suggests that a cranium recovered during the last field season, KNM-ER 1813, may indeed represent that group at Lake Rudolf.

The variety of morphology present in the Rudolf hominid sample poses a number of interesting questions and of these perhaps the most important concerns the relationship between the advanced primitive members of the gracile groups. Does the gracile group contain generically distinct *Australopithecus* and *Homo* or does it contain only one taxonomic group with wide variation due to temporal, behavioural, sexual or geographical factors? Robinson, in placing all of the more gracile types in the genus *Homo* (*Nature*, 205, 121; 1965), has favoured the second explanation. His classification, based largely on features associated with dental mechanisms, implied significant dietary differences between the robust and gracile groups. Leakey now suggests that there may be two gracile groups—one advanced and one with more primitive morphology, distinct at the generic

level—in addition to a large, robust group and perhaps one other. He thus suggests the existence of at least three separate hominid lineages, sympatric and contemporary, within the early Pleistocene. Such a classification imposes problems.

First, it is difficult to understand how the East African environment could provide adequate ecological space to support three or more separate hominid lineages which must have been in competition for territory and for some basic subsistence materials during a period of 2 million years or more. Leakey's interpretation of the evidence would seem to suggest an early adaptive radiation within the Hominidae but since all groups were living in presumably the same environment, it is difficult to visualise the adaptive pressures and isolating factors which are necessary to produce genetic separation in related groups. Finally, and most important, if one accepts that gracile australopithecines and *Homo* coexisted in the early Pleistocene, then one must also accept that the available sample of australopithecines does not, and indeed cannot, represent the ancestral hominid group. The gracile australopithecines are widely accepted as the basal hominid stock and yet Leakey's current classification of the early hominids implies that the known members of this group coexisted with the genus *Homo* and were in fact too late to provide the ancestral population.

The problems associated with interpretations of the Rudolf material demonstrate the urgency of the need to re-evaluate the taxonomic criteria for genera within the Hominidae. The definition of the genus *Homo*, proposed in 1964 by Louis Leakey, Tobias and Napier (*Nature*, 202, 7) is inadequate on several grounds and failed to demonstrate adequate morphological space between the gracile australopithecines and *H. habilis*, the most primitive member of the genus *Homo*. Robinson's classification separated the robust australopithecines ("*Paranthropus*" in his terminology) from all gracile hominids ("*Homo*") on the basis of dietary and behavioural factors. Still others have suggested that all of the australopithecines should be included within a single taxa. There is still, however, no widely accepted classificatory system. The present difficulty is due partly to the inevitable incompleteness of the fossil sample and partly to the inadequacy of Linnaean systematics in dealing with evolving populations; in the particular case of the Rudolf material, Leakey's typological approach to classification adds yet another dimension to the difficulties. Palaeontologists must be dealing with evidence of evolving lineages and yet by continuing to compartmentalise this evidence into discrete taxa based on typologically orientated criteria, they are losing sight of the continuity and cohesiveness of the fossil record. Typological classification emphasises the distinctiveness of the material and must, also, therefore, implicitly suggest discontinuity in the fossil record. A more appropriate approach might emphasise functionally-based similarities and expected variability in evolving populations and would emphasise the continuity of the evolutionary process.

Leakey suggests in this issue that in view of the large amount of fossil human material now available he intends to make a review of hominid systematics. Such a review is necessary, but before it can be of practical importance, the theoretical bases of hominid palaeotaxonomy must be re-evaluated and if necessary reformulated. Without a valid and widely acceptable theoretical framework for classification of the fossil Hominidae such a taxonomic review may be premature and will only add further controversy.

From our Palaeoanthropology Correspondent

Predicting how proteins fold up

In current and pending publications there are signs of a new, more ambitious phase in the struggle to predict the biologically active conformation of a protein from its covalent structure. Certainly there is much incentive for ambitious investigations in this field. In the right conditions, many proteins spontaneously and reversibly fold into their biologically active conformation maintained by intramolecular non-bonding forces and reducible disulphide bridges. Such observations have appropriately been interpreted as evidence that the linear sequence of amino acid residues which comprises the covalent structure of the protein carries all the necessary information for directing the folding process, and it is just a short step to speculation that artificial synthesis or genetic engineering of novel sequences will lead to conformations with novel catalytic and control functions. But which sequences will lead to the desired conformation, and achieve it in reasonable time?

The latest contenders in pursuit of the answer are Ralston and De Coen (*J. molec. Biol.*, **83**, 393; 1974) and Nagano (*ibid.*, **84**, 337; 1974). Both follow current opinion in seeking the answer in nucleation, that is, in centres of conformational structuralisation which initiate and guide the subsequent folding up of the protein molecule.

Ralston and De Coen carry out conformational energy calculations on a variety of possible nucleating structures of varying complexity, though generally on sequence fragments of six or less residue units. Principally, the object of the exercise is to find the favoured (lowest energy) conformation for a variety of short sequences. In order to reduce the computation to reasonable proportions, some severe approximations are made. In particular, these workers exploit the Liquori concept (*Q. Rev. Biophys.*, **2**, 1; 1969) of a stereochemical alphabet in which only a small number of specified conformations is allowed for any amino acid unit and interactions between units merely determine which of these is the favoured one. Furthermore, not all sidechain conformations are adjusted in the search for the lowest energy confirmation, and neither are geometric variables other than rotations around single bonds. A true minimisation of the energy of the overall system could yield rather different results, and it is surprising that these workers do not apply established minimisation procedures even where these could be easily and fruitfully applied. Nevertheless, interesting conclusions are drawn concerning the favoured conformations of many short sequences which could, within much longer sequences, present the first appearance of structural organisation during the folding process and so act as nucleation sites.

It could be argued, however, that work of this kind is premature. Perhaps another, less ambitious phase should properly precede this one—the phase of consolidation of the methods used to calculate the conformational energies. Conclusions concerning nucleation are likely to be no more credible than the least reliable conformational energy function used. Complete substantiation of the results of Ralston and De Coen awaits full minimisation and the advent of more realistic conformational energy functions, or at least the substantiation of those already in use.

For this reason the calculations of Nagano would seem to be on safer ground. Nagano belongs to the school of investigators who predict nucleating structures not on the basis of conformational energy calculations but on the basis of statistical analysis of proteins of known sequence and conformation. A crude example of this type of approach might be the observation that glutamic acid tends to begin a run of residue units in an α -helical conformation, and

therefore it might be predicted to do so in a protein of unknown conformation. The approach of Nagano, however, follows current trends in being much more sophisticated and quantitative, and takes account of the effect of pairs of residue units at different separations along the sequence. In his current paper, Nagano reports on the predictability of α helix, extended chain regions which are potential candidates for β -pleated sheet structures, and looped conformations of the backbone, in proteins of recently determined conformation which do not appear in the data of the initial statistical analysis. How good are the predictions for new proteins of completely unknown conformation or when the conformation, if known, is not taken into account.

Nagano reports that the accuracy of the predictions "seems to depend very strongly on the actual data used", and concludes that his predictions are less reliable for the new proteins. The predictions of α helix are good, however, providing the protein is not rich in β -pleated sheet, and the predictions of β -pleated sheet are good if the protein is not rich in α helix. The 'goodness' of a prediction is assessed in terms of a number of different accuracy statistics.

The results reported are at first glance disappointing to those who have learned from past publications in this field to expect steadily increasing degrees of accuracy. The important point is, however, that Nagano goes on to show that predictability can be enhanced by taking into account interactions between α helix, potential β -pleated sheet and loops. In particular, the consequences of β -pleated sheet structures occurring in the vicinity of α helices are considered. Nagano is therefore taking the first really serious look at the role in the folding of proteins of interactions between nucleating structures. Connoisseurs of the art of predicting protein conformation may feel that there is nothing entirely new in his reasoning, but at the very least Nagano presents a comprehensive preview of the problems to be encountered.

Nagano concludes his analysis of nucleation with a brief discussion of the final stage of protein folding after the topological pathway of the protein backbone in three-dimensional space is roughly determined. Recognising the importance of the close packing of the hydrophobic sidechains during this stage, he would do well to consider the recent papers of Richards (*J. molec. Biol.*, **82**, 1; 1974) and Wishnia and Lappi (*ibid.*, **82**, 77; 1974). Richards presents the most detailed analysis so far of the tight packing of atoms in proteins of known conformation, and he concludes that simple geometrical packing may provide useful criteria in guiding and evaluating trial structures in simulations of protein folding. Wishnia and Lappi, on the other hand, have investigated experimentally the binding of apolar ligands to hydrophobic sites, using the interaction of cyclohexane and n-heptane with α and β -cyclodextrins as a model. If one considers the final stages of the folding of a protein as a folding of hydrophobic sidechains onto a previously established structure with a hydrophobic surface, then it is clear that work of this type will play an important part in providing thermodynamic parameters for the simulation of such a process.

What does seem clear is that the final stages of folding will be the most difficult to consider theoretically and therefore to predict. For simulating this stage of folding, the concepts and parameters obtained through investigations like those of Richards, Wishnia and Lappi will be necessary but not sufficient. The number of conformations to be treated and compared is clearly astronomical, and success will owe as much to the size and speed of future generations of computers as it does to the programs and data fed to them. But it is remarkable that one can now discuss the difficulty of predicting the final stages of folding, not the folding as a whole. This position has been achieved because of workers like Ralston, De Coen and Nagano who have done much towards reducing the number of initial and intermediate conformations in the folding process.

B.R.

Towards improved ways of localising tumours

THERE are many current investigations aimed at improving methods for localising both primary and metastatic tumours. Non-specific radio-labelled proteins, for example, have been used by some investigators (Spar *et al.*, *Cancer*, **20**, 865, 1967; Bonte and Curry in *Radioactive Isotopes in the Localisation of Tumours*, 80, Heinemann, 1967). Recent findings in experimental and human tumour immunology have, however, generated renewed interest in the possible use of specific reagents, namely radiolabelled antibodies, as a novel type of localising agent.

The success of this approach will depend, among other considerations, on the specific activity of the labelled antibody, its specificity for the tumour cells and on tumour site, cell composition and size. Although little success has been claimed for such studies using some experimental tumour systems, specific and significant *in vivo* localisation of labelled antibodies against a tumour-associated transplantation antigen of a methylcholanthrene-induced rat tumour was attained by Izzo *et al.* (*Proc. Soc. exp. Biol. Med.*, **139**, 1185; 1972).

The carcinoembryonic antigen (CEA) is a human oncofetal antigen associated with the glycocalyx of tumour cells, and is released into the plasma and other body fluids. It was originally considered to be associated solely with endodermally-derived carcinomas (Gold and Freedman, *J. exp. Med.*, **122**, 467; 1965); further studies have shown that CEA, or 'CEA-like' materials, are released into the body fluids from a wide variety of neoplastic and some non-neoplastic conditions (see, for example, *Br. J. Cancer*, **26**, 335; 1972). Last year, Primus *et al.* (*Cancer Res.*, **33**, 2977; 1973) reported that a mucus-secreting carcinoma growing in immunologically-depressed hamsters and derived by serial propagation in hamsters from a human

colonic carcinoma, exhibited preferential uptake of radio-labelled heterospecific anti-CEA antibodies. In this week's issue of *Nature*, Mach and his colleagues now report similar findings for a human colonic carcinoma growing in nude mice and that this antibody accretion may be detected by suitable external scintillation scanning equipment. Unfortunately, in both studies, the labelled antibody was not located specifically in tumour tissues and there was a long delay after its administration before optimal tumour content of the label was attained.

Iodine is not the ideal scanning isotope; so far, it has only yielded labelled antibody with a relatively low specific activity. Isotopes with superior scanning properties such as technetium-99m may give better results, although the initial rate of isotope accumulation will be important in determining the usefulness of the method.

Other practical limitations include the presence of significant amounts of circulating antigens which may bind the heterospecific antibody and the presence of appropriate autoantibodies on the tumour cell surface. Both phenomena will serve to decrease the amount of labelled antibody eventually located in the tumours. The studies of Primus and Mach and their colleagues have been carried out in optimal conditions of tumour site and type, yet the smallest detectable lesion weighed 200 mg and was located superficially. Moreover, the presence of extensive tumour necrosis was also a limiting factor which, when considered with the problem of circulating antigen excess, reveals that there are many difficulties to be overcome before hepatic metastatic lesions of colorectal carcinomas with their characteristic central necrosis will be visualised in this manner in patients.

Consequently, this approach to tumour localisation does not have immediate clinical applicability. It does, however, reveal another possible area of fruitful investigation which may eventually yield not only improved diagnostic aids but also therapeutic regimes through the use of antibodies, coupled to anticancer agents.

A.M.N.

Beyond systems ecology

WITH the increasing disturbance of natural systems by modification of the environment, the need for a way to predict the behaviour of complex ecosystems is rapidly becoming paramount. Because of the scale of the problem, the study of ecology is moving away from simplified systems and the analysis of elemental interactions towards systems in which the numbers and kinds of interactions are not under control and cannot be isolated. Extrapolation from two- or three-population models to large scale systems is often inappropriate and can give drastically misleading results.

The first attempts to derive a predictive theory of complex ecosystems were based on techniques well known to engineers under the general heading of systems analysis. A systems model is defined in terms of elements, each of which has one or more inputs and outputs and is specified in terms of the relationships between the various inputs and outputs of each element. With this very broad definition virtually all models are systems models of some kind but the term is usually used in cases where the number of elements in the system is large enough for detailed analysis of each one to be impossible.

Systems models have been applied on a small scale to ecological problems for the past one hundred years or so, usually in agricultural pest control or wildlife or resource management. The emphasis in most of the earlier applications was on the factors which affect a single population, usually one of commercial importance. These systems models were successful and widely used but limited

in extent by the amount of calculation necessary to analyse them. With the development of high-speed computers, Watt of the University of California, Davis and Holling of the University of British Columbia, and others, recognised that systems models in ecology could be used on a larger scale. The logical basis for their approach to the problem is the same as in the simplest models, but the availability of computers made it possible to use the models to determine and use the input-output relationships for all the populations within a community rather than only one of them.

The systems approach to ecology seemed so promising and the need for useful predictive models so great that between 1964 and 1972 funding of participation in the International Biological Program (IBP) has been at the level—unheard of in ecological research—of more than \$40,000,000 per year. Ecologists, engineers, meteorologists and mathematicians were gathered for the study of several systems ("biomes"), such as deciduous forest, intertidal zone, short and long grass savannah and desert. Extensive measurements were proposed as the basis for equally extensive computer models whose value could be determined only by a full scale program.

One of the reasons for the appeal of the systems approach, particularly to those not directly involved in ecological research, is its apparent objectivity. Ideally a systems model could be constructed by somebody with no prior knowledge or intuition of the system he is studying. The relationship between the elements would become clear

after a sufficient number of measurements. Since one of the difficulties in understanding the behaviour of ecosystems is ignorance of potentially important interactions, the systems approach seemed to eliminate any bias by design.

Unfortunately the promise of systems ecology has not been realised. The accumulation of accurate measurements and the construction of the first systems models lead not to useful predictive models of the various biomes but a recognition of the need for more measurements and more elaborate models. The successful systems models reduced the scope and analysed some of the subsystems in detail. Two problems have contributed to the difficulties encountered in the IBP studies. First, although computers are becoming larger and faster, there are still finite limits to the amount of information which can be analysed. The number of potential interactions increases with the square of the number of elements and the addition of one new element to the model requires the measurement of its relationship with all previous elements. Although common sense can reduce the number of interactions without reducing the objectivity of the approach (mice do not directly ingest soil arthropods), the quadratic increase remains. Second, the uncertainty and error inherent in ecological measurements greatly reduces the utility of a large model. A 5% error in each interaction might not significantly affect the predictions of a three-element model, but could invalidate those of a twenty- or thirty-element model.

An alternative to the systems approach has been developed independently by Levins of the University of Chicago and May of Princeton (*Proc. N.Y. Acad. Sci.*, in the press). "Loop analysis", as Levins calls it, is essentially hierarchical and depends on the initial assumption that the interaction between two elements of the system can be determined to be positive, negative or zero. It is thus formally equivalent to analysis of matrices with entries of +1, -1 or 0. In some simple cases, many of the important properties of a system can be determined without knowledge of the strengths of the interactions; the signs are sufficient. Levins (*Stability and Complexity in Model Ecosystems*, Princeton University Press, New Jersey, 1973), describes some examples for which the stability of the system and the sign of response of one of the elements to perturbations of one of the other elements can be determined.

The potential utility of loop analysis is not limited, however, to such simple systems. Although the results for more complex systems may be indeterminate when the behaviour depends on the strengths of the interactions, loop

analysis can identify those interactions or combinations of interactions (loops), which are the most important in determining the behaviour of the systems and thus provides the technique for reducing drastically the number of measurements which are necessary for a predictive model.

There are, of course, limitations to this approach. There is a possible bias introduced by the assumed signs of the interaction terms. There is no objectivity in the initial specification of the loop diagram, so that it is dependent on the intuition of the researcher. This means that it is necessary to investigate the consequences of ignoring certain interactions before reaching any conclusions. Further limitation is that if most of the interactions are in fact important in determining the behaviour of the system, nothing is gained over the systems approach. When a ecological system is inherently complex, loop analysis cannot simplify it, but when the system has had some simple aspects (and many ecological systems do if viewed correctly) then loop analysis can often reveal the simplicity.

From a Correspondent

Narrowest room temperature Mössbauer resonance

from a Correspondent

A RECENT paper by Raghavan and Pfeiffer (*Phys. Rev. Lett.*, **32**, 512; 1974) has shown that the Mössbauer effect can be studied using ^{73}Ge . The 13.3-keV transition to the ground state has long been one of the most attractive candidates for high resolution experiments because of the extreme sharpness of the resonance ($E\gamma/\Gamma_{\text{nat}}=10^{14}$ where $E\gamma$ is the Mössbauer γ energy and Γ_{nat} is the theoretical value of the full line width at half maximum of the nuclear transition), and because the low energy of the γ photon assures that a high probability of recoil-less transitions will result even at room temperature. The observation in this paper that resonance does occur indicates that a potential 28-fold improvement in $E\gamma/\Gamma_{\text{nat}}$ over the 14.4-keV transition in ^{57}Fe is now available. This constitutes a major advance in the search for a high resolution tool for use in physics, chemistry and technology of germanium.

The width of the absorption line reported is about seven times Γ_{nat} but despite this broadening it is the narrowest Mössbauer line observed so far at room temperature. This extremely sharp line could, theoretically at least, measure very small changes in the s-electron density, the electric field

gradient and the magnetic field at the Ge nucleus.

The paper does indicate, however, the severe experimental difficulties involved in the use of this isotope as a source of extremely sharp electromagnetic radiation. In the figure, the $^{73}\text{As} \rightarrow ^{73}\text{Ge}$ decay scheme, recently clarified by the use of high resolution Si(Li) detectors, is shown. The main problems which arise from this decay are, first, the high internal conversion coefficient, α_{IC} , of the 13.3-keV γ photon of 1,100 (that is, only 1 γ photon in 1,100 escapes from the ^{73}Ge atom without being internally converted into an electron); second, the close proximity of the γ -photon energy to the K-absorption edge of Ge ($=11.1\text{-keV}$); and, third, the low natural abundance of ^{73}Ge in natural Ge of 7.6%. Because of the first two problems the resonance cross section is smaller than the nonresonant electronic absorption cross section in Ge at 13.3-keV ($\sigma_{\text{res}}/\sigma_{\text{el}}=0.5$). This is an unusual and unwanted situation in a Mössbauer experiment. In practice, therefore, a choice has to be made between a thin absorber which reduces the potential of the resonant effect or a thicker absorber which will result in a reduction in the spectral quality of the detected photo peak at 13.3-keV. The use of enriched ^{73}Ge absorbers are vital in this work.

Other difficulties arise from the extreme sharpness of the resonance. Narrow lines are only possible if the source and absorber nuclei are sited in environments as free as possible from all sources of inhomogeneous broadening. In the experiments reported, a fairly intense source of ^{73}As embedded in a single crystal of high purity Ge and a single crystal absorber prepared with enriched ^{73}Ge isotope were used. The velocity spectrometer employed a conventional electromechanical drive operating in the velocity range $\pm 88 \mu\text{m s}^{-1}$. This very small Doppler velocity, similar in magnitude to the velocity of the minute hand of a wrist

Energy spectrum of ^{73}As source together with decay scheme of $^{73}\text{As} \rightarrow ^{73}\text{Ge}$ (from Raghavan and Pfeiffer).

watch, is more than sufficient to scan the resonant line. This extremely small velocity range requires the apparatus to be isolated from building vibrations and the equipment was, therefore, set on a pneumatically suspended granite table.

Raghavan and Pfeiffer are optimistic, because of the importance of germanium technology and the extremely high purity and crystal perfection which can now be achieved by this technology, that the 13.3-keV transition of ^{73}Ge will become a powerful new tool in high resolution Mössbauer spectroscopy. The experimental problems, however, are quite formidable. Since α_T is so large, it would seem that a conversion electron detector which would detect the 1,100 internally converted electrons instead of, as in this paper, trying to detect the one resonant γ photon which escapes would reduce one of the experimental difficulties. Possibly one could use a $^{73}\text{Ge}(\text{Li})$ detector as both absorber and detector. There is no doubt, however, that ^{73}Ge Mössbauer spectroscopy does suggest many exciting possibilities to both the theoretician and experimentalist.

Reindeer overgraze in South Georgia

from our Plant Ecology Correspondent

THE introduction of mammalian herbivores by man has resulted in a number of ecological problems in many parts of the world. In the British Isles the introduction of the rabbit, probably in the eleventh or twelfth centuries AD, imposed a new constraint upon the development of many vegetation types. The effects of these animals in modifying the composition of grassland swards was ably demonstrated on the South Downs by Tansley and Adamson (*J. Ecol.*, **13**, 177; 1925) who first used enclosure as a technique for this purpose. Subsequently much work has been done on this subject, particularly since the myxomatosis epidemic of 1954 (see, for example, Thomas, *J. Ecol.*, **48**, 287; 1960; White, *ibid.*, **49**, 113; 1961).

The reindeer is another mammalian herbivore which has been transported to new areas by man, though not as widely as in the case of the rabbit. In 1909 eleven animals were released on the Antarctic island of South Georgia and further introduction continued until 1925 in other parts of the island. The populations have remained isolated from one another, but by 1958 the original Barff Peninsula herd had risen from 11 to 4,000 animals. Numbers have increased even further in recent years since hunting ceased in 1964. There is evidence that sheer pressure of numbers is forcing an extension of

Reindeer grazing *Deschampsia antarctica* sward now invaded by *Rostkovia magellanica* in the Whale Valley, South Georgia. Photograph taken in January 1972 by P. Stone (from Lindsay, *Bull. Br. Antarct. Surv.*, No. 35; 1973).

range despite unfavourable environmental conditions such as steep mountain slopes and glaciers with abundant crevasses.

Lindsay (*Bull. Br. Antarct. Surv.*, No. 35, 101; 1973) has reviewed the effects which high reindeer stock densities may be having on the vegetation of South Georgia. Unfortunately, past documentation of the flora has been largely non-quantitative and this makes it difficult to be sure that vegetation is indeed changing. To supplement this anecdotal evidence concerning the past flora of the island, Lindsay makes a comparison of vegetation in grazed areas with that in similar areas which as yet have no reindeer. This method of approach also has certain disadvantages, for one can never be sure that all other factors are equal in the two sites.

Despite these difficulties, Lindsay does present evidence which suggests that the intensive grazing of reindeer is severely modifying the composition of the vegetation. Some plants, such as *Acaena adscendens* are little changed in overall frequency, but are reduced to a creeping, rhizomatous growth with few leafy shoots. This species was recorded in 1890 as being "richly developed" in the area. In areas of very high stock density, such as the Barff Peninsula, *Acaena* is almost completely eradicated; evidently the constant removal of leafy growth can weaken the species over long periods. Some species such as the grass *Festuca erecta* and the rush *Rostkovia magellanica* are apparently unpalatable and hence have increased in abundance as a result of the reindeer's selective grazing. *Festuca*, however, does seem to be sensitive to heavy trampling.

The most serious effects of grazing and trampling are upon the lichens. Many species abundant in the ungrazed areas are now almost or completely absent from the grazed regions. The

two most abundant lichens affected are *Cladonia rangiferina* ("reindeer moss") and *C. furcata*. The former has vanished completely and the latter is reduced in cover abundance by a factor of ten as a result of the heavy grazing pressures. Experimental work on reindeer in the Arctic (for example, Pagau, *J. Range Mgmt.*, **23** (2), 95; 1970) has shown a similar demise of lichens under heavy grazing and trampling pressures. Such an effect is not of widespread importance in most Arctic areas because the density of reindeer is normally far lower than in South Georgia. For example, caribou in Newfoundland are estimated to have a density of one animal per 110 km²; densities in South Georgia may locally rise as high as one animal per 0.07 km².

The very high densities of reindeer attained in this new environment free from predation is adequate to explain the gross vegetational changes suggested by Lindsay's study. Two lessons should be learned from this work; in the first place the population levels of an introduced animal world should be strictly monitored and controlled and in the second place a more rigorous effort should be made to document the flora and fauna of areas in which such introductions are planned. Only in this way can the native biota be used as a clinical thermometer attesting the health or otherwise of a virgin community placed under an alien stress.

Questioning isostasy

from our Geomagnetism Correspondent

THE observations made by the members of Pierre Bouguer's expedition to Peru between 1735 and 1745 were to lead to the discovery of one of the most important principles in geology. Bou-

guer's principal aim was to measure an arc of meridian, a procedure requiring repeated determinations of the vertical—and he was fully prepared for the local errors arising from the horizontal attraction of the Andes on his plumb-line. But to his surprise he found that the gravitational pull exerted by the Andes was "much smaller than that to be expected from the mass represented by these mountains!" More than a century later, after Sir George Everest had found similar discrepancies in the vicinity of the Himalayas, Airy (*Phil. Trans. R. Soc.*, **145**, 101; 1855) was able to use his "hypothesis of crustal balance" to explain this curious lack of mountain power in terms of an underlying mass deficiency roughly equal to surface load represented by the mountains themselves. Thus was born the principle of isostasy, although the operative word was not coined until more than 30 years later by Dutton (*Bull. phil. Soc. Wash.*, **11**, 51; 1889).

Today, few people would dispute that at equilibrium there exists in the Earth a certain 'level of compensation' above which all columns of material having the same cross-sectional area have the same mass. Moreover, even the old conflict between Pratt's (*Phil. Trans. R. Soc.*, **145**, 53; 1855) suggestion that isostatic adjustment takes place by lateral density variation above a level of compensation lying at constant depth, and Airy's view that the material above the level of compensation comprises a lower density crust overlying a higher density substratum, has been settled to most people's satisfaction by acknowledging that either or both mechanisms may apply in certain circumstances. The basic principle of isostasy is now so ingrained in the fabric of geology that few earth scientists would question that the crust in a region thrown out of isostatic equilibrium by an 'external' force such as glaciation will return to such equilibrium once the force is removed.

But Artyushkov (*J. geophys. Res.*, **79**, 741; 1974) now questions precisely that, arguing that "the isostatic state is generally unstable and differs from the stable position of the crust, which actually exists in many regions". What apparently persuaded Artyushkov to carry out the analysis leading to this remarkable conclusion was the acknowledged fact that, for no immediately obvious reason, many young orogenic regions (the Eurasian Alpine geosyncline zone, for example) are associated with strong isostatic anomalies, even though gravimetric data show the Earth's crust as a whole to be generally close to isostatic equilibrium.

In developing this problem point, Artyushkov notes that in a region whose horizontal scale is several times greater than the lithospheric thickness

the crust will recover equilibrium quite rapidly following the removal of external stress. For a region several hundred kilometres across, for example, the characteristic recovery time following glacial retreat is only of the order of thousands of years. But in young orogenic regions the crust is hotter than normal and the lithosphere is thinner, implying an even more rapid and complete restoration of equilibrium. In other words, the period of crustal recovery in such regions is much less than the typical duration of tectonic activity (10^5 – 10^7 yr), suggesting that on a regional scale the crust should be close to its equilibrium position.

One way of reconciling this supposed equilibrium with the obvious lack of isostasy would be to invoke viscous forces acting on the lithosphere from the asthenosphere, but the creation of the necessary viscous stresses would require improbably high asthenospheric flow rates of greater than 10 m yr^{-1} . Instead, Artyushkov sets out to show that it is a mistake to assume that the equilibrium position of the crust is generally the same as the state of isostatic equilibrium; the two states are physically quite distinct and coincide only in special circumstances.

The core of Artyushkov's case is an extended mathematical treatment of an admittedly simplified model of the Earth's crust floating on the mantle. But it is sufficient to show that large non-hydrostatic stresses exist in the crust and lithosphere because of horizontal variations in crustal and lithospheric thickness and that these stresses are non-uniformly distributed throughout the depth. One consequence is that the crustal/lithospheric layer has two characteristic relaxation times, the first (T_1) being associated with the vertical adjustment of the layer and the second (T_2) with the horizontal spreading of inhomogeneities in the layer thickness. T_1 , which is much smaller than T_2 , is the time associated with the reaching of the 'equilibrium position' (that is, the mechanical equilibrium position) and this state only coincides with isostasy in the special case of a region where the crustal and lithospheric thicknesses are constant; conversely, unless the thicknesses are constant the state of isostatic equilibrium is mechanically unstable.

Because data on the vertical distribution of the stresses in the lithosphere are sparse, it is not possible to compare gravity anomalies predicted by the Artyushkov model with observed anomalies in any great detail, although there is general agreement between the two. Thus the model predicts very low gravity anomalies for platform lowlands located far from mountain regions, negative anomalies of a few

tens of mgal over ocean basins a few thousand metres in depth, and positive anomalies of a few tens of mgal over young orogenic regions—to take just a few examples. Practical demonstrations apart, however, the more important general point is that Artyushkov's analysis offers an explanation, in principle, of certain isostatic anomalies whose existence geologists and geophysicists have very often tended to gloss over. By the same token, it also seems to hit at one of earth science's most cherished principles, suggesting that even the most basic and time-honoured assumptions may benefit from critical re-examination.

Sticks and carrots

from our Materials Science Correspondent

AT a conference on the conservation of materials, sponsored by the Institution of Chemical Engineers and the British National Committee on Materials, on March 26–27 at Harwell, the emphasis was partly on primary metal supplies and the associated topic of substitution, with a low in the direction of plastics. Much of the conference, however, was targeted on the problems, both technical and political, associated with recycling. The political interest in this field was signalled by the opening address delivered by the Chief Scientific Adviser to the Cabinet, Sir Alan Cottrell, and of the Liberal peer, Lord Avebury.

What was for one observer the most interesting issue discussed at the conference was raised by P. F. Chapman (Open University)—a most cogent and persuasive speaker. His primary concern is with the energy content of primary metals implied by the energy input of the extraction and purification procedures. When this aspect is pushed into the forefront, then the systematic recycling of 'energy intensive' metals becomes particularly attractive. The problem is, how are the public and manufacturers to be persuaded to take the necessary steps—domestic conscientiousness and apposite engineering design—to increase recycling substantially?

Chapman quoted the parable of the common. A piece of common land can support twenty-five cows, and five smallholders each have the right to graze five cows there. All is well until one of them adds a sixth cow, to increase his income a little. All twenty-six cows go a little short of grass, including the rogue smallholder's sixth cow, but overall he gains; most of the loss, without any compensating gain, falls on the other four smallholders. In turn, they add cows, until in the end all are worse

off, and the last state is worse than the first for all. This might be a parable for the evils of inflation, but in the present context the point is that the incentive for self restraint is merely collective, whereas each individual in isolation has a financial motive for selfishness.

A case in point is the design of beer cans. Many of these are made of steel, with a top made of aluminium for its easier tearing qualities. Such cans are almost useless for recycling, since aluminium is an unacceptable contaminant of scrap steel. The manufacturer has an incentive to design a can in such a way that the consumer is most likely to buy it (I take it as axiomatic that most canned beer is of indistinguishable and mediocre quality!). The scrap merchant or the British Steel Corporation gains from a prevalence of aluminium-free cans, whereas the beer drinker and the can maker do not, and may even suffer inconvenience.

This last point, the fact that the financial benefit of improvements in the recycling technique does not go to the people who need to modify their behaviour to bring the benefits about, was also made forcefully by J. B. J. Williamson (Guest, Keen and Nettlefolds Ltd). He worded it differently: in the course of materials recycling, ownership of raw material changes from manufacturing industry to the user, until it becomes waste and belongs to everybody and nobody. This is why recycling in the manufacturer's plan ('prompt recyc-

ling') is so much more effectual than 'post-consumer recycling'. A recycling industry is defenceless against the vagaries of the public, and is so vulnerable to a fierce price-war with primary producers that it would have to concentrate totally and would have no scope for diversification—hence would be unattractive for investment. This difficulty is enhanced by the fact that technological improvements by users reduce demand for metals in short supply; thus a new, effective method for joining aluminium cable ends reduced demand for copper cables.

Yet an autonomous recycling industry is bound to come. Williamson was persuasive in arguing that the economic forces of the market will not favour recycling; but recycling will become much more attractive if (1) foreign primary sources become less reliable (he had disruption in mind rather than nationalisation) and (2) governments convert environmental priorities into fiscal incentives and threats.

This will not be easy—Chapman suggested that the building of aluminium smelters in Britain with government backing and incentives led to a reduction of aluminium recycling rather than a reduction in primary imports—but it is essential. Plainly manufacturers and consumers alike must either be cajoled with allowances and other financial incentives (for instance, to use all-steel or all-aluminium cans, and then to collect them after use) or they must be threatened with penalties if they do not

behave. The trouble with the stick is that civil servants have to think up a complete programme of legislation and the police have to enforce it. Yet such a programme can only be based on present technology: as Marx commented, the problem is not to understand the world but to change it, and the advantage of using the carrot instead of the stick—incentives rather than threats—is that industry would have a motive for developing new recycling processes and new manufacturing designs congenial to recyclers. There must be a mixture—but let there be incentives for carrot growers.

Sir Alan Cottrell remarked that the British Government will usually act if they have clear, unambiguous information. It is to be hoped that the Civil Service will provide that information and that legislation will follow.

Dynamics of biomembranes

from a Correspondent

AT an international conference in Titisee on March 21-23 on the dynamics of biomembranes, the proceedings began with a reminder by H. P. Zingsheim (Max-Planck Institute, Göttingen) of the difficulties of attempting to draw conclusions on the molecular structure of membranes from either fixed and stained sections or from freeze fractured preparations. Chemical studies by M. S. Bretscher (University of Cambridge) and investigations with purified phospholipases by R. F. A. Zwaal (University of Bern) which have revealed an asymmetric distribution of phospholipids in red cell membranes were discussed. There is, however, no evidence for similar asymmetry in other cell types: the biosynthetic origin of the asymmetry is also obscure. In connection with lipid phase transitions, D. Chapman (University of Sheffield) reported that transition temperatures can be altered by drugs, especially antidepressants, and H. Träuble (Max-Planck Institute, Göttingen) indicated that lung alveoli may utilise the phase transition properties of surfactant phospholipids during expansion and contraction.

Interesting points were made by E. H. Eylar (New Jersey) on two autoimmune diseases induced by injection of membrane proteins that may normally not be exposed *in vivo* to the immune system, namely, the A1 basic protein of the myelin of the central nervous system and sperm proteins: the sperm proteins have a possible immunological application in the control of fertility. Complex formation of the A1 basic protein with lipids in surface monolayers was dis-

Luminescent echinoderms

Like many other marine animals, some echinoderms are bioluminescent. Herring (*J. Zool.*, 172, 401-418; 1974) has found luminescence in two species of ophiuroids, six asteroids, nine holothuroids and two crinoids. This figure shows the main luminescent areas (stippled) of five asteroids: a, *Cryptasterias personatus*; b, *Plutonaster notatus*; c, *Hymenaster* sp.; d, *Pectinaster forcipulatus*; and e, *Hydrasterias ophidion*. The dorsal surface of *P. forcipulatus* bears fasciculate pedicellariae which do not occur elsewhere on the body but it is not known if they are involved in the luminescent response.

cussed by A. A. Demel (University of Utrecht) who reported that the amino terminal region of the protein seems to interact preferentially with lipids as this region is resistant to trypsin added to the subphase.

On the second day J. A. Lucy (Royal Free Hospital School of Medicine, London) drew attention to the possible role of increased lipid fluidity in membrane fusion. C. A. Pasternak (University of Oxford) then described experiments on membrane leakiness (not lysis) which may be an initial stage in virus-induced cell fusion; he also ventured the opinion that enzymes are not involved in this action of viruses. K. Simons (University of Helsinki) presented findings on the membrane glycoproteins of Semliki forest virus which resemble glycophorin in projecting right through the membrane. Considerable discussion was aroused by his intriguing proposal that release of virus by budding through the plasma membrane may involve recognition and interaction of nucleocapsid proteins with the cytoplasmically-exposed segments of these glycoproteins in the membranes of infected cells.

S. C. Kinsky (Washington University, St Louis) reported important studies on liposomes which he had rendered immunogenic by incorporating DNP-coupled, N-substituted derivatives of phosphatidylethanolamine. Appropriately substituted phospholipids thus seem potentially valuable in immunological studies on haptens: they may also be useful in the radioimmunoassay of drugs. Another investigation on liposomes was described by B. E. Ryman (Charing Cross Hospital Medical School, London) who has encapsulated enzymes within liposomes (of potential use in inborn errors of metabolism), and who is applying encapsulation to drugs, for example, 5-fluorouracil, as this may permit the tissue specific application of relatively small doses of drugs.

Lysolecithin was a recurring topic, and there were discussions of whether or not small quantities might be involved in virus-induced cell fusion, of its acylation with unsaturated fatty acids in thymus cells stimulated by concanavalin A, its possible role in cellular junctions and its facilitation of concanavalin A-induced agglutination in chicken erythrocytes during which H. Fischer and his colleagues (Max-Planck Institute, Freiburg) made several contributions.

A lively exchange centred around the relevance of Mitchell's hypothesis in the transport of galactosides, amino acids and other molecules across membrane vesicles prepared from *Escherichia coli* that is coupled to the oxidation of D-lactate (H. R. Kaback, Roche, New Jersey; W. R. Konings, Haren, Nether-

lands). Finally the mode of action of antibiotics on membranes, which seems still to be a very open question, was pursued by B. Deuticke (Technical High School, Aachen) who concluded that the presence of proteins scarcely modifies the action of these drugs on the lipid components of membranes, and by B. de Kruffy (University of Utrecht) who discussed the formation of some interesting, albeit speculative, molecular complexes of polyenes with cholesterol in relation to their biological activity.

The meeting was sponsored by Dr Karl C. Thomae, Biberach/Riss, subsidiary to C. H. Boehringer, Ingelheim and was organised by L. L. van Deenen (University of Utrecht) with H. Schroeder (Thomae).

Is the bass on the decline?

from our
Marine Vertebrate Correspondent

THE bass (*Dicentrarchus labrax*) is a well known species to the sea angler; it is highly rated as a fighting fish, it grows to a fair weight, and has a relatively palatable flesh. In British waters it is widely distributed, but common only in the south and south-west, although it occurs as far north as Scotland where especially in the north-east it is rare. Until recently, however, its biology was virtually unknown; there were no data on its ageing and growth, little was known about its food, and the only knowledge of its spawning habits and early life was derived from elementary observations. The value of the bass to anglers first prompted research by staff of the Inland Fisheries Trust, Dublin who contributed to knowledge of the bass's biology in Irish waters (Kennedy and Fitzmaurice, *J. mar. biol. Ass. U.K.*, **52**, 557-597; 1972). Knowledge of this fish has now been extended in a report by Holden and Williams on dynamics of bass in English waters (*J. mar. biol. Ass. U.K.*, **54**, 91-107; 1974).

Holden and Williams's study was initiated by the concern expressed by angling bodies at the apparent decline in bass populations in English waters. A programme of tagging was begun with the aid of members of the National Federation of Sea Anglers, in which anglers tagged 954 bass in 1970 and 1971 mainly on the coast of Devon. Of these fish, 59 were recaptured, most (45) within 16 km of their release point and the majority (44) within the year of tagging. The exceptions, however, show that there were long-range movements, some of them over an extended period, the longest being 1,066 days at liberty. Most of the fish represented by returns had evidently made coastwise migrations, although one fish tagged on

the South Devon coast was captured after 222 days in mid-Channel to the west of the Channel Isles.

On the basis of these tagging returns the authors suggest that the life history of bass in English waters falls into two phases. The first is the nursery stage when young fish of about 10 cm length enter estuaries in which they stay for 1 or 2 years, leaving usually as 3-year-old fish. The second phase is one of greater mobility when, as adult fish, they migrate coastwise and even offshore, possibly seasonally.

This synthesis of the first years agrees with the results of Kennedy and Fitzmaurice who also found young bass to live in estuaries, creeks and lagoons, but concluded that mature bass do not make extensive migrations. The different conclusions of Holden and Williams may be due to the fact that the Irish tagging was confined to the southern coasts of Ireland where bass are abundant and present all year round. A substantial part of the tagging effort of Holden and Williams was expended in similar areas of south-west England, however, and the data in confirmation of their theory amount to only 12 returned tags, of which only 6 were of distant migrations. In support of this rather slender data they cite communicated information from another source of three bass tagged off Anglesey which were recovered in Cornwall and Devon, but of this critical evidence no further information is advanced.

Dicentrarchus labrax.

The apparent contradiction between the conclusions of the two groups is important. If Kennedy and Fitzmaurice are correct in assuming that the bass populations are mainly sedentary, then heavy fishing could quickly lead to severe local depletion of the stock. Conversely, if Holden and Williams's conclusions are accepted the stock of bass is at least national, and heavier exploitation can be permitted locally without undue damage. It is unfortunate that in this critical area there is conflict of opinion and little data from which to draw conclusions.

With regard to the alleged decline in bass fishing, both pairs of authors consider the cause to be the failure of successive year-classes caused ultimately by climatic changes. Holden and Williams even venture to predict that if present climatic trends continue, bass could possibly become a rare species even in southern British waters.

Fortification of foods with amino acids

Aaron M. Altschul

Georgetown University School of Medicine, Washington, DC 20007

In this article Dr Altschul discusses how the addition of specific amino acids can solve some nutritional problems, chiefly by reducing the pressure on protein produced from the land.

FORTIFICATION (or supplementation) of a food with amino acids is a process whereby the limiting deficiency of amino acids in a diet is eliminated or reduced by adding small amounts of one or a small number of amino acids. As such it becomes a practical tool for selectively improving the protein component of a diet without requiring the addition of other amino acids or food components already present in adequate amounts. Usually, the deficiencies of one protein source are balanced, in part, by mixing with one or more other protein sources which contain an excess of the amino acid deficient in the first: corn plus beans, or a cheese and bread sandwich, for example. The result is the creation of a new mixture of better protein value than the first. The use of specific amino acids allows adjustment of the amino acid composition in the protein to the exactly desired balance, that is in balance with the second limiting amino acid. Such adjustment introduces another option for increasing protein supply at low cost.

Supplementation with amino acids is normal practice in formulating animal feeds¹. For example, corn and soybeans are the major energy and protein ingredients in nonruminant feedstuffs in the United States. When soy represents a substantial portion of the protein in the mixture with corn, then methionine is limiting; addition of DL-methionine improves the protein quality of that mixture. When soy provides a small proportion of the protein in the diet, the mixed feed does not provide enough lysine to balance the deficiency of lysine in the corn. In such circumstances addition of lysine is required for optimum nutrition. This can be obtained from fish meal or by addition of the amino acid itself.

Addition of amino acids also can be part of a system of improving the quality of human diets. Addition of methionine makes certain legume foods better sources of protein. It has been suggested that the addition of less than 1% of methionine to manioc flour would improve the value of cassava bean diets in Brazil by improving the protein quality of the beans². Bread supplemented with lysine is a far superior source of protein than ordinary bread. Fortification may be a means of reducing the cost and improving the delivery of protein in institutional meals and could also improve the special delivery systems organised for infant and maternal feeding or for feeding of the aged.

Hegsted³ estimated that white flour containing 3.2% utilisable protein will have its protein impact increased to 5.3% on addition of 0.2% L-lysine·HCl. On this basis it can be estimated that the one million tons of wheat consumed in Tunisia annually would gain the equivalent of 20,000 tons of utilisable protein by addition of lysine. Relief shipments of grain to avoid famine can be made more complete sources of nutrients, particularly protein, by fortification either at the point of shipment or at destination.

Nutrition is not merely calorie or protein nutrition; it is meeting the total nutrient requirements of the body. Thus, mechanisms which allow addition of amino acids to

single foods or diets can also be the means of adding other micronutrients such as vitamins and minerals.

The literature on amino acid fortification has been reviewed extensively⁴⁻⁷. Eight essential amino acids—leucine, isoleucine, lysine, methionine, valine, threonine, phenylalanine and tryptophan—are required by human adults; histidine is required in addition by infants. The highest requirement for the infants is leucine and the lowest is tryptophan. Adults require less protein and less of the essential amino acids—19% as essential compared with 40% for the infant—and the spread in requirements among the essential amino acids is also less than for the infants. Radical departure from the optimum pattern can cause amino acid imbalance with many consequences including reduced growth^{8,9}. This can result from excessive addition of a single amino acid to a diet or from complete reliance on single sources of protein such as corn¹⁰. Thus, any supplementation with amino acids must be controlled to avoid such imbalance.

Amino acids rarely occur free in nature; they are supplied as proteins in food. Essential amino acids and the nitrogen required for growth and maintenance of body tissue nitrogen are thus supplied by the food protein. Amino acids may also be supplied as protein hydrolysates or as mixtures of free amino acids, the latter either orally or parenterally. The metabolism of amino acids presented as proteins differs somewhat from that of free amino acids, particularly in the treatment of temporary excesses, but all the evidence supports the idea that for practical purposes amino acids in proteins and free amino acids can be considered as interchangeable¹¹.

Certainly there is every evidence that a food protein supplemented properly with amino acids will have the expected improved impact. Many generations of rats have been raised on totally synthetic diets in which proteins were completely replaced with specific amino acids and other sources of nitrogen¹². Humans have been kept in nitrogen balance by completely synthetic diets consisting entirely of the essential amino acids and other nitrogen sources¹³. Infants grow normally on wheat protein plus lysine as the sole source of protein¹⁴. However it is measured, the fact emerges that plant sources of protein properly supplemented with amino acids are adequate to support growth in animals and man.

Amino acid supplementation in practice

By far the greatest utilisation of pure essential amino acids has been in animal feeds; the most used has been methionine. The United States consumes about 22,000 tons of DL-methionine annually; world capacity is 92,000 tons¹⁵. Prices for DL-methionine are in the range of \$1.20 to \$1.60 per pound. Recently, as the price of soy has increased, formulas are being reconsidered to use the least amount of soy protein necessary to complement the amino acids of corn. For many feeding purposes the protein content of the diet can be relatively low; the soy then is required primarily to furnish tryptophan; the deficit of lysine can be overcome by providing additional L-lysine. Consumption of lysine in the United States is at the level of 6,000 tons annually at a price of \$1.00 to \$1.60 per pound.

TABLE 1 Estimates of cost of fortifying cereals with amino acids

Case 1: Rice²⁹

Ingredients	Cost Assumptions	Cost Estimate
Rice (milled)	\$200 per 1,000 kg	
L-Lysine HCl (0.15%)	\$1.80 per kg	\$13.60 per 1,000 kg
		or
L-Threonine (0.05%)	\$19.40 per kg	6.8% of cost of rice
Fortification granules and cost of addition to rice	\$1.20 per 1,000 kg	

Case 2: Wheat*

Wheat	\$200 per ton	
L-Lysine HCl (0.23%)	\$10 per ton of wheat	
Vitamin A (250 million IU g ⁻¹) (0.033 g kg ⁻¹)		\$12 per ton.†
		or
Niacin (0.019 g kg ⁻¹)	\$2 per ton of wheat	6% of cost of wheat
Riboflavin (0.0025 g kg ⁻¹)		
Thiamin (0.0016 g kg ⁻¹)		
Iron (0.055 g kg ⁻¹)		

* P. R. Crowley, personal communication.

† Cost of ingredients includes cost of preparing and adding a premix.

Methionine has been added at 0.5% of soy protein in infant formulas; such formulas have been judged equivalent in protein value to the proteins of meat, eggs, and milk¹⁴. Interest in applying lysine fortification to human foods is relatively recent and coincided with the development of methods for the production of L-lysine at practical costs. It was recognised early that lysine supplementation offered an unprecedented opportunity to improve protein nutrition, particularly for those who could not afford adequate protein and who depended heavily on cereals for most of their calories and proteins¹⁷⁻¹⁹.

The applications are few however. Some cold breakfast cereals and breads are fortified with lysine in the United States. There are instances of rice and noodle products fortified with lysine in Japan. Certain Incaparina formulas are fortified with lysine²⁰. Interest in amino acid fortification of human foods is certainly on the increase but at the time of writing, the utilisation of this option is at too low a level to make a significant contribution to human protein supply.

The economics of amino acid fortification of human foods are complex. The population is heterogeneous compared with the homogeneous animal populations; different human age groups differ in their requirements of protein and lysine. Moreover, not all diets are always deficient in protein. The poor, and particularly the vulnerable among them, are most likely to be deficient in protein. Amino acids improve protein quality, they add no calories to the diet; thus, it is difficult to compare in a general way costs and benefits of this approach to nutrition compared with other options. The comparison must be on specific approaches to well-defined groups.

Issues surrounding amino acid fortification

The main issue is how to use amino acid fortification to advantage to provide more protein at a lesser cost to people who do not get sufficient. Since this will involve a government decision to allocate scarce resources or to modify regulations involving addition of amino acids to the food supply, the ease and rapidity with which such a positive decision is made depends in part on the nature of the consensus among scientists who advise government. The following are some of the issues being discussed within various countries and in United Nations' agencies regarding amino acid supplementation of foods.

Calories or protein This involves amino acids only peripherally. The question is whether the most important deficiency in the diets of poor nations is protein or calories.

Amino acid addition represents the extreme of adding protein under circumstances where no additional calories are provided.

Concern for the protein aspect of malnutrition was intensified by the discovery of the aetiology of kwashiorkor, recognition of its wide distribution in underdeveloped countries, and the realisation that clinical protein-calorie malnutrition is only a small aspect of a more general syndrome involving specific protein deficiency²¹. More recently, important members of the nutrition community have insisted that the major problem in poor countries is lack of calories, that the protein quality is adequate, and that what is needed is more of the same kind of food²². Latest revisions of standards of protein requirements for normal healthy humans are lower than before^{23,24}. Although there are many uncertainties, such as the increased needs of the sick and the relationship between minimal and optimal protein nutrition, the tendency is to translate such nutritional judgements into recommendations for public policy.

The meaning of 'more of the same kind of food' needs more inquiry. The proven existence, or lack, of protein malnutrition is just one part of the issue. The major problem is the interdependence of calorie and protein supply: there is a protein-calorie tradeoff. This occurs because calories are cheaper than protein. Poverty forces a reduction in the amount of protein food consumed (legumes or animal products) in favour of the cheaper foods (cereals, root starches and sugar).

Stress for more calories challenges agricultural capacity to maintain quantity and quality of protein supply. Increased population demands an increased food supply merely to maintain nutritional conditions at the existing level. But there is no unlimited ability to expand food production. The great increase in grain production—the "Green Revolution"—which has unquestionably had a great impact on food availability has come about because high yield varieties of wheat and rice were planted. These required more fertiliser and energy input and more irrigation. More acreage was put into grain production at the expense, in some instances, of that devoted to legume production.

In India, for example in the sixties, *per capita* calorie availability fluctuated around 2,050 kilocalories: first dropping to 1,950, rising to 2,200, and then returning to 1973 estimates of 2,050. Protein availability remained about the same in that decade at about 53–55 g *per capita* per day. This is a great achievement considering the population increase during this period, but percentage of protein from pulses (legumes) decreased from 23% in 1959–61 to 15% in 1973. Without a compensatory increase in animal protein, this trend represents a serious threat to protein balance, particularly to the lysine content of the diet²⁵. An FAO report of projections of percentage of calories as protein in South Asia lists this value as decreasing from the present 10.2% to 9.8% in 1980 (ref. 26). As the percentage of protein calories is reduced, more reliance is placed on cereal protein and less on concentrated protein sources such as legumes and animal proteins, which also have an excess of lysine. Therefore, not only is the percentage of protein as part of the calories reduced but also the quality of the protein. The reduction is far more serious than the numbers would indicate.

Added to this problem is the increasing demand for protein by nations whose income *per capita* is increasing. Those that have had high incomes for some time have enjoyed a high protein intake gained at the expense of huge excesses of cereals to feed the animal population. In the United States approximately one ton of cereal is available *per capita* but only about 150 pounds are eaten each year by humans directly; the rest is fed to the animals. The grain equivalent calories required *per capita* per day in the developed countries can be estimated as 8,000 kilocalories

compared with 3,000 for the underdeveloped countries^{27,28}. As their income increases, other countries are trying to catch up, as evidenced by the increased sales of cereal grain and protein concentrate to Russia and Japan, as well as Western Europe. Thus, there is the situation where, almost explosively, the world has been forced to recognise a worldwide shortage of protein or the ingredients with which to produce it. The United States had a temporary embargo on the export of protein-rich commodities and feedstuffs in the summer of 1973.

In the face of such developments it is inconceivable that any country or any group can say that there is no protein problem. Certainly, planning on that basis courts disaster.

Natural or synthetic sources of amino acids There is a preference to obtain the deficient amino acids by breeding them into the plant rather than by supplementation. This idea has attractive features. It departs least from the norm: the corn, wheat or rice is almost the same, but has more protein and lysine. If this could be achieved finally without any reduction in yield for the particular crop, then this is indeed the best idea.

The cereal most advanced in this direction is corn. High lysine corn has made considerable progress²⁹. Nevertheless, the new corn has not been planted in a practical sense any more than amino acid fortification has been instituted, because in most instances the yield is less, there are some problems of acceptance of conventional food products derived from these varieties, and there is need for social organization to ensure that the correct seeds are planted and sold. Whether or not it will ultimately be possible to develop the improved corn so that it will yield and maintain increase in yield as well as the ordinary corn remains an open question. At present yield per acre is all-important. A more likely outcome could be a combination of breeding for improved quality with fortification to complete the process.

Unfamiliarity with the concept Supplementation with amino acids or vitamins and minerals is an unfamiliar concept in most places. To increase familiarity and provide a means for seeing what could happen in reality, three field trials have been organised by the Agency for International Development (US) in cooperation with the United States Department of Agriculture, several governments and their scientists, academic institutions, and some industrial firms providing ingredients and technology^{30,31}. These involve addition of lysine and vitamins to wheat flour in Tunisia; fortification of rice with vitamins, lysine, and threonine in Thailand by mixing synthetic granules with natural rice in the village mill³²; and fortification of corn at the village mill with small quantities of soy flour plus lysine in Guatemala.

In all instances baseline data are being obtained on the populations, particularly the children, and information is being collected on the cost of fortification, its effect on the amino acid composition of the food supply, and on whatever changes can be determined in health status that might be attributed to improvement in the protein value of the foods. It is realised, of course, that measurement of changes in an entire population and the determination of the important cause and effect relationships is difficult, if not impossible. Certainly, that fortification with amino acid improves the protein value of a cereal is beyond doubt. The issue is the degree to which the effect of nutrition intervention alone on public health can be determined.

Cost Since the object of amino acid fortification is to reduce the cost of protein for those who can least afford it, government subsidies are involved, so the cost of amino acids and lysine, in particular, is critical. Sample calculations of the cost of fortification of wheat and rice are given in Table 1.

Slessor³³, in his discussion of energy subsidy in food production, considered the case of fortification of 'Food for Peace' shipments of wheat from the United States in 1966. To have fortified 30×10^9 pounds of wheat with 32×16^9

pounds of lysine would have required an energy subsidy of 390×10^9 kilocalories, and this would have provided a nutritionally feasible diet for one hundred million people. He also said that the same energy subsidy expended in the importing country on marginal grassland could produce 38 pints of milk per person. Extrapolation of the calculation derived earlier³ to this case shows that the fortification route provides a gain of 6.3 pounds of useable protein *per capita*; the same amount of subsidy would yield 1.2 pounds of milk protein *per capita*.

Amino acids are produced either by fermentation or by direct synthesis³⁴⁻³⁶. Lower levels of production favour fermentation; at greater concentrations, economies of scale favour synthesis of lysine. Thus, the generator for cost reduction will be the volume of amino acids utilised in animal feeding. Mitsuda and Yasumoto⁷ and Durrenmatt³⁷ showed that the trend of production cost of other synthetic nutrients would suggest a further lowering in cost of lysine. It has been estimated that in large scale production, lysine can be produced for about \$0.50 a pound or less.

Present world lysine production capacity is estimated as 16,000 metric tons annually¹⁵. It is predicted to reach a level of 60,000-70,000 tons by 1980, primarily because of increased demand as a feed supplement. In some areas demand far outpaces supply; in France the price of L-lysine quadrupled to \$9.30 per kilogram in 1973.

No substitute for aesthetics The supplementation of cereals or foods is a completely nutritional manoeuvre. It is not visible; and that is its advantage as it requires no change in eating habits, but by the same token, it is difficult for a government to claim credit for such expenditure without obvious immediately visible beneficial results.

This is not a manoeuvre equivalent to adding meat to the diet, or legumes. Calculations can be made of the meat or milk equivalent in protein added to a nation by fortifying a given cereal grain supply with an amino acid. From a strictly protein point of view, these might be correct. They are not, however, entirely correct because the meat adds calories and other nutrients as well as improving the protein quality of the cereals. More importantly, meat adds variety and a psychological stature to a diet which no amount of fortification can induce. There is no doubt that the use of animal protein as a means of improving cereal protein is the preferred way of improving diets when income is increased.

It is tempting to conclude that where the quest for aesthetic satisfaction in foods predominates, no amount of fortification, be it with amino acids, vitamins, minerals, or protein concentrates, can gain the political support that nutritional considerations warrant. It would, therefore, be expected that fortification will make the greatest initial progress in countries and socioeconomic groups where there has been a modicum of aesthetic satisfaction in foods and where aesthetics are no longer the burning issue. Yet, the appreciation of nutrition as apart from eating as an essential component of public health measures is probably far greater than assumed. It is possible, therefore, that in some areas a purely nutritional measure can gain political support on its own public health merits.

Projections

The two basic constraints on increased food production are land and energy, and the two are interrelated. Where shortages of the two exist, in the short term the picture is grim. Increases in yield were made possible by engineering food plants to withstand and derive benefit from increased energy inputs. An improvement in the present land constraints requires that plants be engineered for higher photosynthetic yield at constant energy input. The development of new sources of energy which will change the nature of the energy constraints is the most likely long term effect. The practice

of using more nonagricultural inputs to maximise food production will continue. Just as this trend will be reflected in optimum use of water, fertiliser, insecticides and fungicides, so will it by increased usage of nonagricultural food nutrients to enhance the quality of the products of the farm.

It has been estimated that 10,000–20,000 tons of L-lysine will, by 1980, be added to cereals intended for human food¹⁵. The rapid proliferation of animal analogues from soy and other vegetable protein sources will increase the use of methionine in foods based on the meat and milk model³⁸.

Fortification with amino acids alone obviously does not solve all problems of nutrition. It does not provide calories. It does not provide aesthetic satisfaction in foods except where it contributes to the development of meat and milk analogues. It is no substitute for better distribution of wealth either within a country or worldwide. But it is a way of reducing pressure for protein from land. It could be considered by some as a temporary measure to bolster protein supplies until more attractive options become available. But, fortification with amino acids will probably become an essential and regular adjunct of human food systems. In this way, technology will contribute more flexibility to counteract the pressures of greater populations and higher expectations. Nevertheless, the pressure of population constitutes a burden that no amount of technology can expect to overcome indefinitely without a genuine lowering in the quality of life for almost everyone.

Nutritional lessons from the Ethiopian drought

J. B. Mason & R. W. Hay

University of Cambridge and Medical Research Council, MRC Dunn Nutrition Unit, Cambridge, UK

J. Holt, J. Seaman & M. R. Bowden

London Technical Group, 55 Evelyn Gardens, London, UK

The drought in Ethiopia and the subsequent international reaction has drawn attention again to the urgent need to consider methods of early assessment of and appropriate responses to such situations. Assessment requires the collection of reliable data; responses should pay attention to established nutritional principles and take account both of the situation as it exists and of the normal dietary patterns.

THE population of Ethiopia is 25.2 million¹, of whom at least 90% live by subsistence farming. Ecologically there are a number of different zones, distinguished particularly by altitude and by local variations in climate. In the northern area, where relief efforts were concentrated in 1973 (see Fig. 1), there are broadly three zones: highland (above about 2,500 m), lowland and desert. The farming pattern is mixed: the main food supply is from crops of cereals and legumes in the highlands and lowlands, with increasing amounts of livestock

as the altitude decreases. The two food sources, crops and animals, are interdependent in that oxen are essential for cultivation. The desert people are largely nomadic herders, dependent on cattle and trading with some agriculture, and form a distinct group: they have had limited contact with the mainstream of Ethiopian life, and regard themselves as a separate community.

The land is intensively cultivated and there has been progressive deforestation and soil erosion. Even under normal climatic conditions little excess of grain is produced, particularly in lowland areas, and usually there is a hungry period of one or two months when the previous year's stocks of grain have been exhausted and the next harvest is not yet ready. Excess of livestock creates a little wealth: during times of shortage, animals are sold for meat and hides to buy grain when necessary, albeit at high prices.

The community was particularly vulnerable to climatic change. Between 1966 and 1973 the rainfall was erratic, resulting in poor harvests and inadequate grazing for livestock; local food shortages occurred periodically during this time, leading to population movements and government relief.

There are two annual harvests in most parts of Ethiopia, associated with the main rains (occurring between July and September) and the short rains (usually falling at some time between February and April). The harvest from the main rains, gathered in October to December, provides much of the food supply for the following year, supplemented by crops sown during the short rains; this latter harvest is also of critical importance in providing seed for the main sowing later in the year.

In early 1973 the short rains failed completely in many areas, particularly in Wollo and Tigray provinces. The harvest in late 1972 had been generally poor, and with the subsequent failure of the 1973 early harvest food stocks began to run out, particularly in the lowland areas, from April onwards. In the desert the drought probably had an even more disastrous effect in that little or no grazing remained by the early part of the year. Serious disruptions of the normal market equilibrium occurred. The cost of grain bought by merchants and sold in the large towns rose steeply, while the price obtained for cattle, sold in order to buy grain, fell from Eth\$ 120–150 to about Eth\$ 10. The abattoirs were unable to cope with the influx, so that many cattle, already in very poor condition, died before they could be slaughtered.

In the period from April to August increasing numbers of people, their food supplies in their villages exhausted and their cattle dying from starvation and disease, made their way to the roads and on to the towns. Little information was available as to the conditions in the countryside away from the roads, although it was assumed that many must have died. It was therefore clear at this stage that immediate action was required to prevent widespread malnutrition.

Faced with large numbers of refugees from the drought-affected areas crowded into the towns, sleeping in the open, the local authorities erected temporary shelters. By September, more than 60,000 people were accommodated in 12 shelters in Wollo alone. Food supplies had not yet been established and the construction of latrines was begun through force of circumstance after the shelters were already occupied, resulting in a high incidence of enteric infections. At the beginning of the rains each year there are anyway sporadic epidemics of enteric infections; these and other diseases common in crowded conditions added to the public health problems in the camps.

In April 1973 an Ethiopian government report indicated the seriousness of the drought and food shortage in Wollo, Tigray and northern Shoa provinces. Distribution of grain was begun by the authorities and outside food aid sought; later seed for the next harvest was also distributed. A relief fund and relief committees were established, and considerable

sums of money raised within Ethiopia. It was estimated from official records that nearly 2 million people were affected, and the grain requirement was calculated as of the order of 50,000 tonnes a month. Nothing like this amount was available and the problems of distribution were enormous. Mission and other organisations were receiving reports of drought and starvation, and were also active in providing supplies and help. The drought in the Sahel area was receiving much attention, and in July a meeting in London discussed "Drought in Africa"², including Ethiopia. By September there was widespread concern over the situation in Ethiopia, and further information was forthcoming, notably from UNICEF. At this time national and international agencies became involved, and aid began to arrive in quantity in October. By the beginning of 1974 teams from Britain, Germany, Holland, Switzerland, Australia, the United States and elsewhere were represented, most arriving several months too late to help the Ethiopians with the main problems, which were at their peak before the 1973 harvest. Relief was required both in the camps and in the remote rural areas but until recently was restricted almost entirely to the camps. Here the need was most obvious but their total population after October was not more than 15,000, less than 1% of the affected population.

The areas of interest concerning nutritional relief are

- defining the situation with respect to the nutritional status of the population, and
- deciding on the appropriate response in terms of food aid.

Assessing the situation

Most assessments of the situation were obtained from official records in centres of population, and from subjective individual reports. The frequently-quoted figure of 50,000–100,000 deaths (see, for example, ref. 3) was obtained from the records of a few towns, scaled up by an estimated factor to represent the total affected population. Rural conditions could only be assessed from nutritional surveys.

The available information indicates that by October 1973 stock losses of at least 80% had occurred in many areas, that 50–70% of the land was planted, and that the harvest, although better than the previous year, was only moderate. The yield from the harvest was expected to last until around March to May 1974. The reasons for the reduced yield were lack of oxen for ploughing, lack of seed, and poor rainfall.

Results of a survey in Tigray showed that of the rural population the very poor—those without land or livestock—were receiving only about half their required dietary intake, less than 1,000 kilocalories per adult per day and 50 kilocalories per kg per day for children; only one meal a day was usually being eaten. The major part of the population, the farming community, was faring a little better, relatively few of them being of less than 70% weight-for-height, and their dietary intake was marginally adequate, of about 1,500 kilocalories per adult per day, 75 kilocalories per kg per day for children; two meals a day were generally being eaten. The salaried (5–10%) workers were receiving up to 3,000 kilocalories per adult per day.

There was a proliferation of idiosyncratic methods of assessment of nutritional status and much nonquantitative subjective data. Standardisation of survey technique is important and perfectly feasible; nutritional survey methodology is an established aspect of nutritional science⁴.

Principles of nutritional surveys. In a situation of developing food shortage time-consuming detailed investigation before action may be unacceptable and crude rapid estimates may be required. Once action is established, aid and more thorough survey work can be concurrent, and indeed survey data is of vital importance in monitoring the effectiveness of the aid.

The primary environmental influences on nutritional status are dietary intake and the occurrence of disease; other

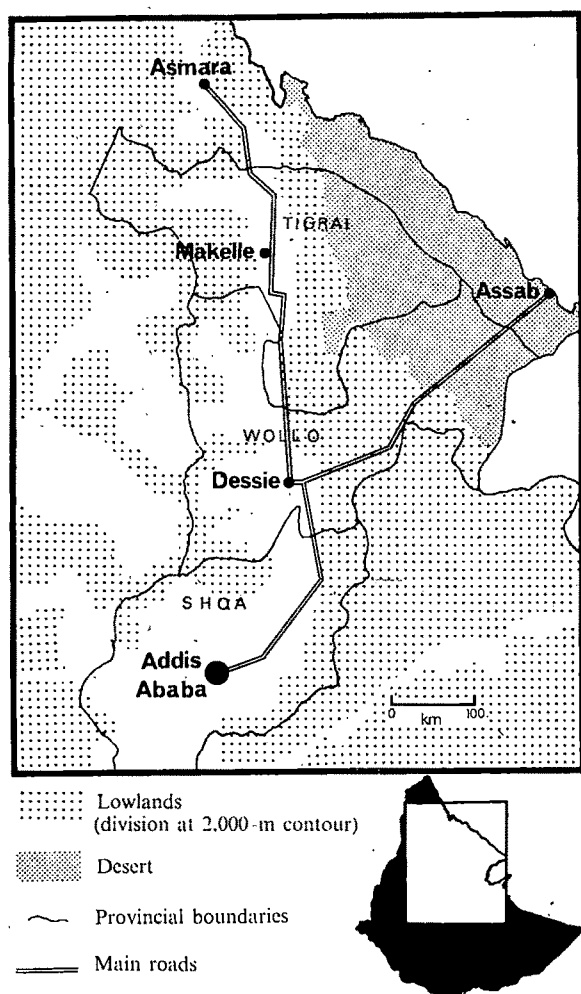

Fig. 1 Northern Ethiopia, showing area known to be affected by the drought in 1973. Highlands are unshaded.

factors—economic, agricultural, social and so on—necessarily exert their effect through either the dietary intake or the disease pattern (see Fig. 2). The nutritional status of the community defines the situation at a point in time but gives no idea as to trends. Current dietary intakes, food stocks and potential supplies provide the primary information as to the likely immediate trend of the nutritional status. The factors affecting nutritional status, shown in Fig. 2, also indicate the points at which action can be taken. Short term efforts, as in relief, are intended to influence dietary intake and disease patterns directly, by feeding programmes and public health measures. Longer term development work attempts to tackle the basic causes of malnutrition.

Nutritional status. The two characteristics of protein-energy malnutrition (PEM), wasting and oedema (associated with hypoalbuminaemia) require separate assessment. The wasting component of PEM is readily determined by anthropometric methods. Weight-for-height and height-for-age measurements ideally define both wasting and stunting⁵ but for a rapid assessment in an acute situation weight-for-height is the most useful measurement. The level of 70% weight-for-height is frequently taken to be approximately equivalent to the conventional 60% weight-for-age level used to define marasmus⁶. The risk to development of oedema (preclinical kwashiorkor) cannot be assessed by anthropometry; blood samples and determination of serum albumin values are required⁷.

Examination for clinical signs of PEM, together with anthropometry, defines the incidence of severe PEM in the community. The most relevant clinical signs are pitting oedema, generally appearing first on the dorsum of the foot,

and severe wasting, detected on the buttocks as 'baggy pants', when the skin hangs in loose folds; the appearance of this sign occurs at around 70% weight-for-height. Vitamin and mineral deficiencies are assessed by clinical examination.

Dietary intakes. Quantitative estimates of dietary intakes can only be obtained by home visits, in which the quantities of food eaten are weighed: nutrient intakes are then calculated from food tables^{8,9}. The two important parameters to consider are the total energy intake and the protein adequacy of the diet, estimated as effective protein concentration (Net dietary protein calories % or NDpCal%).

Community data. Questionnaires for home visits and for interviews with local officials and at health centres give data regarding current food stocks, livestock losses, expected harvest yields, population movements, patterns of disease and malnutrition and mortality rates.

Sampling. The validity and applicability of survey results depends on the sampling methods. Even in preliminary surveys, where the application of strict sampling techniques may be limited by the urgency of the situation, some attempt at randomisation is essential. Stratification by area and within the community can be based on existing demographic, geographical, agricultural and other data, and survey design can then concentrate the effort to manageable proportions. It is inadequate to try to gain an impression without selected home visits, since the most visible members of the community will tend to represent the extremes of nutritional status.

Conclusions from surveys. Such survey data define the current nutritional status of the community, the current dietary intakes and hence the trend in nutritional status of the current food stocks (livestock and crops), and the projected food supply in the immediate future.

The usefulness of survey data as a basis for planning depends on its quality. Rapid initial assessments not only become dated but are unlikely to be authoritative enough to support detailed planning.

Whether a situation requires special action (relief) depends on a consideration of the 'usual' situation in such areas. An assessment of a 'famine' situation perhaps depends on the extent to which the normal equilibrium has been disturbed, and in particular on the ability of the farming community to survive and to recover. The levels of hardship which are unacceptable and which should lead to relief being given require urgent consideration by aid-giving organisations.

Planning

Effective planning of relief is clearly essential but in an urgent situation it may involve particular problems of donor-recipient relationships. The decision to request aid may itself be difficult to take, and the recipient will rightly wish to direct the aid in accordance with its own priorities. These priorities may not agree with those of the donor countries, particularly if the donors are insensitive to local requirements. This can lead to poor coordination and a reduction in immediate and longer term gains. Responsibility for internal administration and coordination lies with the recipient. To ensure a maximum effectiveness, adequate planning and consultation are vital and prior consultation concerning Ethiopia's real needs has often been notably absent.

Successful planning requires that the problem be defined and priorities for action established; where possible these should also advance the longer term development aims. Only then can the appropriate responses be decided.

Nutritional responses

Food aid requested in 1973 was for both grain and 'high protein foods'. Quantities of grain were based on estimated requirements of 0.4 to 0.8 kg per head per day, supplying about 1,500 to 3,000 kilocalories per head per day. At 0.5

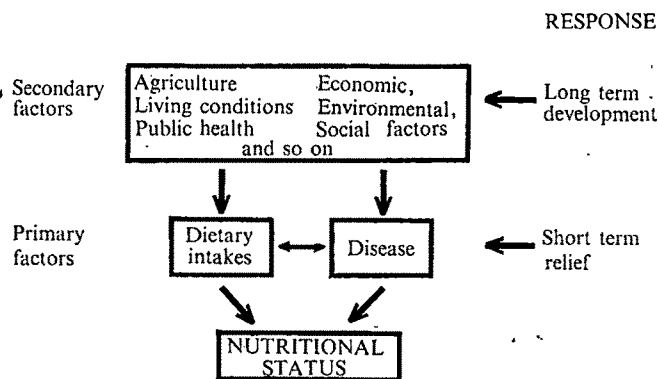

FIG. 2 Exogenous influences on nutritional status and levels at which efforts are directed to improve it.

kg per head per day 1,000 tons would supply 2 million man-days; thus a population of 1 million would require 15,000 tons a month, or 100 5-ton truck-loads a day. The main outside supplies were from international agencies, particularly World Food Programme, which consigned 20,000 tons of grain, of which 10,000 arrived in 1973 (enough to supply the estimated 2 million affected for 10 days, even if it could be distributed.) Further supplies of several thousand tons were redistributed in Ethiopia, and some hundreds of tons of specifically high protein food, designed originally as protein supplements, were also distributed.

It is estimated that about a quarter of the population of the affected areas will require food aid in 1974, and 150,000 tons of grain has been requested accordingly, on the basis of 0.4 kg per head per day; further supplies of protein foods have also been requested from international agencies.

The food supplied to the camps by the government provided 2,000 to 3,000 kilocalories per adult per day, as grain (mainly wheat and maize). At first it was difficult to prepare the food in a form regarded as suitable for main meals but the familiar 'enjera' (made from fermented grain) and 'wot' (a sauce containing legumes, spices and sometimes oil) were later introduced by the Ethiopian Nutrition Institute and were greeted with great enthusiasm.

The choice of foods imported and distributed by most external agencies showed an overemphasis on providing protein, regardless of energy intakes, particularly since the local protein supplement 'Faffa' was available to meet any extra protein requirement. Examples of foods supplied by foreign agencies are sweetened milk, protein biscuits, baby foods packed in individual portions, protein 'tonic' (containing 90% protein of unspecified origin) and, of course, dried skimmed milk. These were neither locally acceptable, nor suitable for treatment or prevention of malnutrition, nor indeed had most of them been requested. Further anomalies, such as the attempted further fortification of the local protein supplement with protein 'tonic', and the provision of exclusively protein supplements (in one case giving twice the protein and half the energy requirements) resulted from the misconception that the malnourished require only protein (and perhaps vitamin pills, which were also used incorrectly).

Principles of emergency food aid. In an acute food shortage, food aid is required

- to support the nonmalnourished population—'maintenance feeding', and
- to improve the nutritional status of the malnourished in the population, 'rehabilitation feeding'.

Both quantity and quality of dietary intake need consideration.

Distribution of supplies as widely as possible is clearly preferable to central cooking and feeding, in order to prevent migration and to enable the population to re-establish its normal food supply. Indeed the effective distribution of

supplies can be of critical importance in stimulating recovery from an emergency. The nutritional requirements for both maintenance and supplementary feeding are similar whether the supplies are distributed or prepared centrally, as in camps.

Maintenance. Maintenance feeding involves supplying either the total dietary intake for those completely dependent on relief supplies, such as nutritional refugees in camps, or in supplementing an inadequate diet when there are some resources locally available. Nutritional requirements for maintenance are derived from recommended intakes published by FAO/WHO¹⁰; these are for 3,000 kilocalories per adult per day, and 70–100 kilocalories per kg per day for children, depending on age. As an approximation 2,000 kilocalories per head per day (for example, from 0.6 kg of grain) irrespective of age would be a minimal allowance on a population basis. An effective protein concentration (NDpCal%) of 5% is recommended for all except children of up to 1 year and pregnant and lactating women, who require an NDpCal% of about 6–8. Cereals alone provide an NDpCal% of about 5 and are thus nutritionally adequate to support most of the population. Inclusion of legumes in the diet would increase the protein concentration (see ref. 11) and conform to normal dietary patterns: if 25% of the grain were replaced by legumes the NDpCal% would be at least 8 and thus the protein requirements of vulnerable groups would be met.

Thus the choice of foods for maintenance is based on supplying an energy intake of at least 2,000 kilocalories per head, with an effective protein intake that need be no greater than 8%. (The typical NDpCal% of high protein foods is at least 20%). The choice then depends on the availability, cost, and on the normal dietary patterns and thus acceptability of different foods. For Ethiopia there is no doubt that the main supplies that meet these criteria are cereals, such as wheat, and legumes (peas, beans and so on) with smaller quantities of vegetable oil and spices.

Rehabilitation. The nutritional requirements for improvement of nutritional status are higher than for maintenance, particularly to allow malnourished children to catch up lost growth. Increased dietary intakes can be achieved by 'supplementary' feeding of extra food for mild cases of malnutrition or by 'therapeutic' feeding for the most severely malnourished.

Energy intakes in excess of 100 kilocalories per kg per day for children, with a net NDpCal% of 8–10%, are required; in fact, rates of catch-up growth are approximately proportional to the energy intake above about 100 kilocalories per kg per day. When, as in Ethiopia, wasting is the main feature of the malnutrition, the overriding requirement is for increased energy intakes. If the total food intake is reduced extra protein is anyway wasted since it is used for energy. The key to supplying extra energy is to provide vegetable oil.

For supplementary feeding extra rations or meals should be provided for selected groups or individuals. For malnourished children it should be possible to increase energy intakes to 120–150 kilocalories per kg per day, with an NDpCal% of about 8. The choice of foods is similar to that for maintenance feeding, with greater emphasis of acceptability since the malnourished are frequently also sick and may have poor appetites, and the energy concentration of the diet should be increased with oil. In Ethiopia a sauce of high oil content, and thus high energy content, was readily constructed by a modification of the usual recipe. There is no advantage in using premixed foods for supplementary feeding; they have generally low acceptability and are expensive.

Therapeutic feeding requires organisation at an individual level and can only be carried out successfully within some centralised system. It is intended only for treatment of the most severely malnourished, who would normally be hospitalised if possible and who require intensive feeding in order to recover at all. Therapeutic diets are made up from fortified milk mixtures, having an NDpCal% of about 8 and providing

at least 150 kilocalories per kg per day for children. These diets are only applicable when a treatment system can be established, as was done in several camps in Ethiopia (see, for example, ref. 12); in this case use of a premixed diet is justified since the administration of correct and known quantities of nutrients is essential. If a system cannot be established for correct administration there is little value in using therapeutic diets.

Proper response

The nutritional consequences of the drought in Ethiopia have again (compare ref. 13) demonstrated the need for nutritional surveillance in assessing relief situations, for adequate planning and for appropriate responses in terms of food aid, based on an assessment of the situation, on a consideration of the normal dietary patterns and on sound nutritional principles. A rational and measured approach to relief is possible based on established principles and greater consideration of these could ensure that relief is more effective.

Plate movement and continental magmatism

J. C. Briden

Department of Earth Sciences, University of Leeds, Leeds LS2 9JT, UK

I. G. Gass

Department of Earth Sciences, The Open University, Walton Hall, Milton Keynes MK7 6AA, UK

Extensive magmatic and metamorphic events have occurred within the Earth's continental crust far from plate margins. During the last 800 million years Africa has only been host to such events during the breaks in the systematic motion of the African plate. This suggests that sublithospheric heat sources have little effect on a moving plate and can only produce recognisable effects in the upper crust if focused for long periods on the same part of the lithosphere.

SEISMICITY, tectonism and magmatism are now concentrated near plate margins. This may have been so throughout much of geological time. Within-plate continental magmatism and metamorphism are commonly believed to be associated with continental rifting¹⁻⁶ but only when rifting proceeds to the stage of transcontinental fracture is the association with plate margins clear.

This paper has three purposes. First, we emphasise that magmatic, tectonic and metamorphic processes have been and are active within continental plates and are by no means exclusively concentrated near plate margins, whether successful or abortive. Second, we note the circumstances in which this activity has occurred, using as an example the magmatic, metamorphic and palaeomagnetic history of a single continental mass, Africa, during the past 800 million years (m.y.). Third, we suggest that this behaviour is to be expected on the basis of thermal convection models of plate motion.

Magmatic and metamorphic activity in Africa

A wide range of igneous and metamorphic rocks are suitable for radiometric age determination. A plot of frequency of radiometric dates against time (Fig. 1) can therefore be used to indicate fluctuations in the intensity of thermal activity in the upper crust, though this cannot be regarded as an accurate quantitative measure. Nevertheless, Fig. 1 shows clearly that within the past 800

FIG. 1 Cumulative histogram of African radiometric age determinations for the period 0-800 m.y. BP.

FIG. 2 a, Regions (stippled) of Africa which have been affected by the pan-African (650–400 m.y.) tectono-thermal event (after Clifford⁷). b, Areas (stippled) of Mesozoic igneous activity (200–100 m.y.) (after Cox⁸ and Black and Girod⁹). c, Areas of Tertiary to Recent volcanic activity 25 m.y.–present (after Le Bas¹⁰ and Gass¹¹).

m.y. Africa has been the site of three main thermal episodes in the approximate time ranges 650–400, 200–100 and 25–0 m.y. before present (BP). The areas affected by these events are shown in Fig. 2. Magmatic or metamorphic activity between 400 and 200 m.y. BP and between 100 and 25 m.y. BP is sparse^{7–11}.

Pan-African tectono-thermal event¹². Igneous and metamorphic rocks over most of Africa (Fig. 2a) yield K–Ar ages in the range 650–400 m.y. BP. Metamorphic rocks are the more abundant and their K–Ar ages record a thermal imprint on host rocks which Rb–Sr and U–Pb analyses indicate to be much older¹³. Kennedy¹² recognised that progressive regional metamorphism, ophiolite sequences and molasse-type sedimentation, which commonly characterise orogeny, occur only in restricted areas, such as the Lufilian¹⁴ and Pharusian^{15,16} chains in central and western Africa respectively. Elsewhere the event occurs as thermal reactivation of much older basement with extensive metamorphism and production of granitic magmas but little or no deformation. Even, however, if the Lufilian and Pharusian chains were the sites of pan-African subduction the amount of closure was small if palaeomagnetic evidence that Africa maintained the same approximate configuration throughout is accepted¹⁷.

Mesozoic magmatism. Between 200 and 100 m.y. BP magmatic activity was intense and widespread in southern^{18,19}, western and possible north-eastern Africa (Fig. 2b). For southern Africa, Cox¹⁰ concluded that igneous activity took place throughout the 200–100 m.y. time range and calculated that the erupted lava once covered 1.4×10^6 km². These rocks are mainly basaltic, but silicic varieties also occur and these may have been produced by anatexis of sialic crust¹⁰. Rocks of similar age in West Africa are predominantly silicic with only minor basic volcanic representatives. In both regions the activity was at its greatest between 200 and 180 m.y. BP and from then on generally waned, with occasional resurgences, until it ceased about 100 m.y. BP. Although this activity heralded the rupture of Gondwanaland, magmatism was not restricted to regions close to eventual plate margins. On the contrary, the bulk seems to have occurred within continental regions, which remained unified throughout.

Late Tertiary to Recent magmatism. Except in Libya where some volcanic rocks date at 40–50 m.y. BP, and Ethiopia where restricted volcanism might possibly have persisted throughout the Tertiary, rocks of magmatic origin in the age range 100–25 m.y. BP are extremely rare. Volcanic rocks with ages of less than 25 m.y. are, however, abundant (Fig. 2c). They are usually found where the underlying and commonly peneplain crystalline basement has been updomed, in places by as much as 3 km (ref. 11). Uplift usually preceded volcanism. Many of these areas of uplift and volcanism, such as Tibesti, the Hoggar and Air massifs, and the Bayuda and Jebel Marra, are completely within the African plate and any fracturing does not extend far beyond the limits of uplift. In eastern Africa the areas of

uplift around the Red Sea and in Ethiopia, Kenya and Tanzania overlap, and the resultant fracture zones join to form the East African Rift System. Beneath these rifts, sialic crust has been markedly attenuated although complete lithospheric rupture has only occurred under the Red Sea and Gulf of Aden. In every case the initiation of uplift and volcanism took place beneath what was then the unified Afro-Arabian lithospheric plate, and constructive plate margins only developed as events progressed.

Apparent polar wander

The apparent polar wander path for Africa since 750 m.y. BP^{17,20,21} is reproduced in Fig. 3. Many of the data were derived from the igneous rocks discussed in the preceding section and are thus well suited to the comparisons discussed here.

The palaeomagnetic poles derived from the Mbozi complex in Tanzania (743 ± 30 m.y.) and pre-Nama dykes in south-western Africa (653 ± 70 m.y.) both lie near the present pole. So also do well defined poles from several less well dated rock bodies in the Sudan, Tanzania and Zambia. It therefore seems that around 700 m.y. BP the pole (which is the South Pole) remained near the present North Pole for about 100 m.y., although age uncertainties prevent a positive conclusion.

Poles calculated from many African rocks ranging in age from 630 ± 24 m.y. to late Ordovician (approximately 450 m.y.) lie in or near western Africa. Although the precise form of this part of the polar wander path is not clear, the concentration of poles in this general area is established. It can therefore be inferred that the pole shifted from its position at 700 m.y. during the late Precambrian. The intervening polar path is, however, strewn with a number of pole positions derived from nominally Cambrian rocks from South America and the shift in question might therefore be as late as mid-Cambrian.

The polar path then moves to the vicinity of South Africa. The date of the shift is uncertain and has been variously estimated as late Ordovician²², Siluro-Devonian²³

FIG. 3. Palaeomagnetic apparent polar wander path for Africa (thick solid line) from 750 m.y. BP to the present; data from compilations^{17,31,39,40} and recent original papers^{28,41,42}. Elaborations of parts of this path suggested by Piper *et al.*¹⁷ (---), and McElhinny *et al.*²¹ (·-·-) are not well substantiated. South American poles, supposedly of Cambrian age, rotated for closure of the South Atlantic, are denoted by x.

and Devonian^{24,25,26}. During the mid-Carboniferous²⁷, the pole is known to have moved away from South Africa, and therefore the estimates of the time for which it remained in that area range from only a few million years to rather more than 100 m.y.

Data from all parts of Africa except the north-east, confirm that the pole reached the vicinity of 60°S, 85°E at the beginning of the Mesozoic and remained there, essentially stationary, until about 110 m.y. BP (refs 21 and 24).

It essentially reached its present position by 40 m.y. BP, and it has stayed there ever since²⁸. This is reflected in the cluster of poles near the South Pole, shown in Fig. 3. The fact that their mean is some 5° from the geographic pole may be because of the inadequacy of data or persistent non-dipole elements in the palaeomagnetic field, rather than because of any true polar wander or plate motion²⁹⁻³¹.

There were thus at least three periods of time within the past 750 m.y. during which the palaeomagnetic pole did not move systematically relative to Africa, but instead either stopped or moved circuitously (Fig. 3). These periods occurred around 500 m.y. ago (at least 530-450 m.y. BP and perhaps as long as 630-400 m.y. BP), from 220 to 110 m.y. ago and during the past 40 m.y. Two other possible pauses in apparent polar wander, around 700 and 350 m.y. ago, have also been mentioned but the evidence for them is less secure. It is incorrect to translate apparent motion of the palaeomagnetic pole relative to a crustal plate, into direct estimates of the speed of the plate motion. To do so requires complete knowledge of the tectonic rotation poles, which describe the motion of the plate through time. Nevertheless, it seems realistic to equate episodes of rapid apparent polar wander with episodes of rapid plate motion. Similarly, it can be presumed that a plate has remained essentially stationary during an interval for which all palaeomagnetic poles are statistically indistinguishable.

Plate motion and thermal activity

The three major African igneous and metamorphic episodes coincide quite precisely with pauses in the systematic motion of the African plate (Fig. 4). In the case of the interval 600 to 400 m.y. the scatter of palaeomagnetic data is such that random or circuitous motion within about 2,000 km of the calculated mean position cannot be ruled out. But for the later two episodes the data suggest that motions of more than a few hundred kilometres are improbable. Each pause in systematic motion follows a period of substantial shift, and is succeeded by a new shift in a different direction. Despite the statistical uncertainties in radiometric dating and in palaeomagnetic estimation of latitude, and the impossibility of determining ancient longitude from palaeomagnetism, this remarkable time correlation is unlikely to have arisen by chance.

The evidence thus suggests that changes from one regime of plate motion to another were not accomplished rapidly. During the transitions, motions were either more complex or ceased altogether. This conclusion is intuitively sensible considering the enormous mass inertia of the system and has been advanced⁴³ to explain a correlation between bends in the Canadian polar wander path and orogenic events.

It also seems that extensive magmatism and metamorphism within the African plate only developed during these transitional periods. This might be anticipated when the enormous thermal capacity of the system is considered. From the general character of the global geological record it is clear that the lower crust and uppermost mantle are normally below their solidus temperatures. As the heat produced within the continental and oceanic lithosphere accounts for only about 65% and 3% respectively of the observed surface heat flow³², the fundamental requirement for magmatism

Fig. 4 Above, schematic representation of the erratic character of apparent polar wander (generalised from Fig. 3). Below, simplified cumulative frequency histogram of radiometric age determinations (based on Fig. 1). Vertical lines emphasise the correlation between the breaks in apparent polar wander and the start of thermal activity.

and metamorphism at high levels in the crust is a substantial heat source beneath the lithosphere. The fact that these effects are regionally restricted at particular times indicates that such sources are unevenly distributed. Our observations also imply that the heat sources have maximum effect when they are applied beneath the same region of lithosphere for many millions of years. Only then does large scale mantle or crustal anatexis occur. These in turn give rise to thermal metamorphism within a few kilometres of the surface. Whether the heat sources begin as localised hot spots of asthenospheric or deeper origin^{3,4,33-35}, or as more extensive asthenospheric upcurrents of a nascent plate-driving system, is not critical in this context. It is, however, pertinent to note that the ultimate source of the Mesozoic Karroo magmatism might have been as deep as 500 km (ref. 19).

For the thermal source and the target to be fixed relative to each other, either both must move together³⁶ or, as is contended here both must remain stationary with respect to the rotation axis of the Earth.

The identification of linear age trends along particular lines of igneous activity³⁷ does not invalidate our main conclusions. Such trends are rare, have been disputed^{36,38} and in any case are short when compared with the dimensions of the igneous provinces as a whole.

If thermal conduction were the only heat transfer mechanism, there would be a time lag of the order of 10^8 yr before sublithospheric thermal events permeated to the surface. The effects could be localised and accelerated by convective heat transfer in the asthenosphere and by upward magma migration. Although it is tempting to suggest that time lags are in fact observed between apparent cessation of African plate motion at 220 and 40 m.y. and the surges of subsequent igneous activity at 200 and 25 m.y. respectively (Fig. 4), this inference is probably unjustifiable on the

evidence available. Certainly no such effect is evident for the pan-African event.

Nevertheless, our analysis demonstrates that widespread continental igneous activity could be the result of stationing a plate over a heat source of a kind which could, potentially, cause continental breakup. It is suggested that thick continental lithosphere will not inevitably break in response to such heating. Instead it may become locally elevated, the thermal gradient may become enhanced and extensive anatexis may be produced as well as widespread thermal metamorphism of pre-existing rocks of the upper crust.

Further evidence of Lower Pleistocene hominids from East Rudolf, North Kenya, 1973

R. E. F. Leakey

National Museums of Kenya, PO Box 40658, Nairobi

Twenty new hominid specimens were recovered from the East Rudolf area in 1973. New evidence suggests the presence of at least three hominid lineages in the Plio-Pleistocene of East Africa.

THIS is a report of the 1973 field season at East Rudolf, Kenya, where the East Rudolf Research Project (formerly Expedition) has now concluded its sixth year of operations. Eighty-seven specimens of fossil hominid were collected¹ from the area during 1968-72; a further twenty specimens were recovered between June and September 1973 from the Upper, Lower and Ileret Members of the Koobi Fora Formation². Exploration to the south of Koobi Fora was begun in 1972 and continued in 1973. No hominids have yet been found

in the limited exposures of the Kubi Algi Formation. A notice of two specimens—KNM-ER 1510 and 1590—that were previously¹ mentioned only by number, is included in this report. The 1973 hominids are not here attributed to genera as there are still no clear generic diagnoses available for fossil hominids. With a few exceptions, previous attributions for the East Rudolf hominid collection remain satisfactory.

Archaeological investigation during 1973 was extended under the direction of G. Ll. Isaac, with J. C. W. Harris who conducted major excavations at several sites in the Upper Member of areas 130 and 131. Limited excavation, but extensive prospecting, in the Lower Member produced sufficient results to support further searching for artefacts below the KBS Tuff.

TABLE 1 1973 hominid collection from East Rudolf

KNM-ER No.	Specimen	Area	Member
1800	Cranial fragments	130	Lower
1801	Left mandible, P ₁ , M ₁ , M ₂	131	Lower
1802	Left mandible, P ₁ -M ₂ and right P ₃ -M ₂	131	Lower
1803	Right mandible fragment	131	Lower
1804	Right maxilla, P ₃ -M ₂	104	Upper
1805	Cranium and mandible	130	Upper
1806	Mandible	130	Upper
1807	Right femur shaft	103	Upper
1808	Associated skeletal and cranial fragments	103	Upper
1809	Right femur shaft	127	Lower
1810	Proximal left tibia	123	?Lower
1811	Left mandible fragment	123	?Lower
1812	Right mandible fragment and left I ₁ and M ₁	123	Lower
1813	Cranium	123	?Lower
1814	Maxillary fragments	127	Upper
1815	Right talus	1	Upper
1816	Immature fragmented mandible	6A	Upper
1817	Right mandible	1	Upper
1818	I ¹	6A	Upper
1819	M ₃	3	Upper
1820	Left mandible with M ₁	103	Upper

During the palaeontological survey, which was supervised by J. M. Harris, all identifiable fragments from certain horizons were collected; new species were recorded and some primate remains were recovered during a limited survey of the Kubi Algi Formation. A detailed account of the East Rudolf fauna will be presented upon conclusion of current studies, but there are clear indications that at times the palaeoenvironment differed from that of the lower part of the Shungura Formation of the Omo Valley in Ethiopia.

In the geological studies, emphasis was placed on microstratigraphy and palaeoenvironmental reconstruction. B. Bowen supervised a study of the Lower and Upper Members of areas 130 and 131 which included confirming the stratigraphic relationships of the cranium KNM-ER 1470. The complete section of the Koobi Fora Formation exposed in area 102 was studied by a group from Dartmouth College, New Hampshire, under G. Johnson. A. K. Behrensmeyer completed a preliminary geological investigation of the hominid sites, noting depositional environments and possible association of fauna; further studies are planned.

I. Findlater extended mapping of tuffaceous horizons to the south of Koobi Fora and collected samples for isotope dating. A series of dates has been obtained from material collected during 1972 (unpublished work at Miller, Findlater, Fitch and Watkins). Palaeomagnetic studies complement those of 1972 and there are sufficient data for internal correlations to be made³.

Hominid collection

Specimen KNM-ER 1590, reported previously¹, consists of dental and cranial fragments which were collected from area 12, some metres below the KBS Tuff. Both parietals, fragments of frontal and other pieces of cranial vault, the left deciduous c and dm², the left and right unerupted C, P³ and P⁴, and the erupted left and right M¹ and left M² were recovered. Although the cranium is immature, it was large with a cranial capacity as great as that determined for KNM-ER 1470. The parietals may show some deformation but, in any event, they suggest that the cranium was wide with a sagittal keel.

KNM-ER 1510, also reported previously¹, includes cranial and mandibular fragments. The specimen is poorly mineralised and further geological investigation at the site indicates a Holocene rather than an early Pleistocene provenance as originally thought.

The 1973 hominids and their stratigraphical positions are listed in Table 1. Specimens from area 123 are rare, and their stratigraphical position relative to the Upper and Lower Members of the Koobi Fora Formation needs clarification.

A well preserved mandible (Fig. 1), KNM-ER 1802, was discovered by J. Harris *in situ* below the KBS Tuff in area 131. The dentition is only slightly worn, and fragments of both M₂ crowns suggest that death occurred before full eruption. The canines and incisors are represented by roots and by alveoli filled with matrix. The mandible shows some interesting features—moulding of the mandibular body, absence of a strong post-incisive planum, the development of a slight inferior mandibular torus and the distinct eversion of the mandibular body when viewed from below.

A weathered mandible, KNM-ER 1801, bears some resemblances to KNM-ER 1802, but its worn dentition and loss of surface bone prevent direct comparisons. The relative proportions of the molars and premolars may have been exaggerated by interstitial wear.

A crushed maxillary fragment, KNM-ER 1804, with P³-M² preserved was discovered by R. Holloway. The teeth are complete but worn.

A skull (cranium with associated mandible), KNM-ER 1805, was discovered by P. Abell *in situ* in the BBS Tuff complex in area 130. The specimen is heavily encrusted with a hard matrix and will require careful preparation before its morphology is revealed. Comments here are thus preliminary. The cranium is in pieces which fit together. After preparation, it should be possible to determine the endocranial capacity; at present, a volume of 600–700 cm³ is suggested. The supraorbital region, much of the face and the greater part of the basi-cranium have not been preserved. The postorbital region is preserved and the minimum breadth is approximately 90 mm. No distinct temporal lines cross the frontal area although they can be discerned and are still apart at the bregma. There are distinct parasagittal crests. The nuchal attachments are very distinctive and protrude to form a wide bony shelf. The palate is intact; all the teeth are preserved except for the right P⁴ and the left I¹. The mandible, small and distinctly robust, is represented by both sides of the body but, except for the right M₂ and M₃, the tooth crowns are missing. The ascending rami are not preserved. The right M₃ and M₂ are well worn but small. The upper dentition shows wear on all the teeth, including M³.

FIG. 1 Mandible, KNM-ER 1802. a, Superior view; b, inferior view; c, right lateral view.

FIG. 2 Cranium, KNM-ER 1813. *a*, Right lateral view; *b*, superior view; *c*, occlusal view of left side of palate.

A large mandible, KNM-ER 1806, was discovered by Meave Leakey at the same site and horizon as was KNM-ER 1805. There are no tooth crowns preserved and the ascending rami are missing in this otherwise complete specimen. The mandible is typical of the large East Rudolf hominid that I have previously attributed to *Australopithecus*.

A fragmented specimen, KNM-ER 1808, was discovered in area 103 by Kamoya Kimeu. The specimen includes maxillary and mandibular teeth, cranial and mandibular fragments, a fragment of atlas vertebra, the distal half of a femur lacking the condyles, a large segment of humerus and other postcranial fragments. There is little doubt that the various pieces are from one individual and further sieving and excavation will be undertaken in the hope of recovering more material.

A cranium, KNM-ER 1813 (Fig. 2), was discovered *in situ* by Kamoya Kimeu in area 123. The specimen was fragmented but has been partially reconstructed. Plastic deformation is evident. The cranium is partly covered with a thin coat of matrix and considerable preparation is needed before a detailed description can be attempted. The endocranial volume is likely to be small; a figure of approximately 500 cm³ is suggested on the basis of comparative external measurements. Other interesting features include the curvature of the frontals, a postglabella sulcus and the small dentition. The maxilla has well preserved teeth, P³-M³, on the left side, but on the right side only the tooth roots and the complete crown of M³ remain. Both canines and lateral incisors are present but the central incisors seem to have been lost before fossilisation. Both sides of the maxilla fit together to give the form of the dental arcade. The right maxillary fragment includes the malar region and connects with the lateral margin of the right orbit.

Other specimens recovered during 1973 are listed in Table 1 and will be described in detail after studies are completed.

Significance of the 1973 collection

In previous reports^{1,4-7}, the East Rudolf hominids were assigned to *Australopithecus*, *Homo* or indeterminate (the last category included both very fragmentary specimens and those of uncertain taxonomic rank).

The East Rudolf specimens that have been attributed to *Australopithecus* span a period of time from 3 million years to just over 1 million years with apparently little morphological change. This form is likely to be the same species

as *A. boisei*⁸; it also shows similarities with *A. robustus* from southern Africa. A Pliocene origin is suggested for this specialised group.

Specimens attributed to *Homo* have been recovered from deposits covering a similar time span, but these show greater morphological variability. Those recovered from the Ileret Member seem to differ from those recovered from the Lower Member of the Koobi Fora Formation. The suggestion that a large brained, fully bipedal hominid was living at East Rudolf 3 million years ago was put forward after the 1972 discoveries⁷. This point of view is supported by the cranial fragments, KNM-ER 1590, also from below the KBS Tuff, and this specimen is provisionally attributed to *Homo*.

The 1973 collection from East Rudolf raises many questions. The new mandible, KNM-ER 1802, could be considered as belonging to the same genus and species as KNM-ER 1470 and 1590. There are striking similarities between the dental characters of KNM-ER 1802 and some specimens from Olduvai Gorge such as the type mandible of *Homo habilis*, OH 7. Although the suggested cranial capacity for *H. habilis* is appreciably smaller than that determined for KNM-ER 1470, the discrepancy may be due to the fragmentary material upon which the former estimates were made. I consider that the evidence for a 'small brained' form of *Homo* during the Lower Pleistocene is tenuous.

The cranium, KNM-ER 1813, may prove to be quite distinct from the robust australopithecines and from *Homo*, as represented by KNM-ER 1470. The dentition is 'hominine', yet the cranial capacity appears small. The cranium has some of the features seen in the gracile, small brained, hominid *Australopithecus africanus* Dart, from Sterkfontein.

I have previously questioned the validity of a distinct gracile species of *Australopithecus*⁶, but this new evidence reopens the possibility of its existence. Some authors^{9,10} have suggested that *Homo habilis*, particularly OH 24, shows features typical of *Australopithecus africanus*. My suggestion here, that *H. habilis* may have affinities with KNM-ER 1470 and 1590, refers only to OH 7 and OH 16. Features of the calvarium of OH 24 show similarities with KNM-ER 1813. The size and morphology of the teeth of the two specimens are alike and the cranial capacities may also be comparable^{11,12}.

The skull KNM-ER 1805 is undoubtedly important, but its interpretation is enigmatic. Its relatively large cranium bears sagittal and nuchal crests but has small teeth; this combination is in contrast to all the specimens previously recovered from East Rudolf.

In any consideration of the affinities of the East Rudolf hominids, the question of sexual dimorphism must not be overlooked. There does seem to be evidence for quite marked sexual dimorphism in one hominid group as demonstrated by the East Rudolf crania, KNM-ER 406 and 732⁵. Unfortunately both crania lack teeth so that the dental characteristics of the alleged female are far from clear.

The possibility of more than two contemporary hominid lineages in the Plio-Pleistocene of East Africa may now have to be recognised, whereas previously one, or at most, two forms were assumed. The attribution of isolated teeth may thus become even more difficult than it is now. Postcranial identifications likewise may be difficult, although the proximal femoral material continues to suggest a morphological dichotomy.

I suggest the following as a basis of nomenclature for Plio-Pleistocene hominids. One genus would include much of the material currently referred to *Australopithecus robustus* and *A. boisei*. A second genus would incorporate many of the gracile specimens from Sterkfontein presently referred to *A. africanus*, perhaps certain specimens from East Rudolf including KNM-ER 1813, and possibly some from Olduvai such as OH 24. A third genus, *Homo*, would incorporate specimens such as KNM-ER 1470 and 1590 from East Rudolf

and possibly OH 7 and OH 16 from Olduvai. Some material from South Africa might also be considered within this last category together with later specimens from Olduvai and East Rudolf. The unusual mandible KNM-ER 1482¹, together with the specimen from the Omo area referred to *Paraustralopithecus*¹³ and certain other specimens from Omo which are contemporary with the three groups just mentioned, could be considered a fourth form—a remnant of an earlier population that disappeared during the early Pleistocene. All these forms may be traced back well beyond the Plio-Pleistocene boundary.

These remarks are necessarily speculative. A more detailed review of hominid systematics is being prepared in collaboration with B. A. Wood. The wealth of data now available presents a new era in the study of early man. The complexities of dealing with the enlarged sample are challenging, and isolated studies on specific specimens must be replaced by exhaustive studies on all the fossil hominid evidence.

I should like to express appreciation for the financial backing provided by the National Geographic Society, the National Science Foundation, the W. H. Donner Foundation and others. The support and encouragement of the National Museums of Kenya and the Kenya Government

made the research possible. Members of the East Rudolf Research Project are too numerous to thank individually but all play a part in a successful field season and are thanked along with those who made important discoveries. I would also express thanks to my wife Meave who, as always, provided invaluable assistance both at the museum and in the field.

LETTERS TO NATURE

PHYSICAL SCIENCES

Years of peak astronomical tides

THIS investigation stems from an obscure statement by the late D. H. Macmillan in a semi-popular book on tides¹. He stated (page 48) that the years when the tide-raising forces reach their greatest peak values occur at intervals of very roughly 16 centuries, and gave a sequence of dates starting with 3500 BC and ending with 1433 and 3300 AD. He did not describe the exact terms of the calculation but merely suggested that they involved coincidence of perihelion (closest approach of the Earth to the Sun) and zero solar declination (Sun crossing equator), which is in fact impossible within the given range of dates. (The longitude of perihelion crosses the equator at intervals of about 105 centuries and will next do so in 6581 AD). Further, if one computes the lunar and solar elements for 3300 AD, for example, one finds that they are not particularly favorable for large tides.

To clarify the situation I must first resolve a paradox. By simple consideration, the greatest tide-raising forces must occur when the Moon and the Sun are in conjunction with the Earth and are at their closest respective distances. But it is also common knowledge that the greatest 'perigee-spring tides' (spring tides coinciding with a close approach of the Moon) occur at the equinoxes when the Sun crosses the equator, which as mentioned above cannot coincide with the closest approach to the Sun around the present millennium. The solution lies in the fact that the equinoctial condition maximises only the semi-diurnal components of the tide at the expense of the diurnal components. Since most parts of the ocean have a magnified response to the semi-diurnal frequencies, one must therefore look to the equinoxes

rather than perihelion for the greatest ocean tides. Then, all the major 'harmonic constituents' μ_2 , $2N_2$, N_2 , M_2 , L_2 , S_2 , K_2 are nearly in phase, and the only loss due to the slightly more than minimum distance of the Sun would be an unfavourable phase for the constituent T_2 , which is practically negligible because it has a typical amplitude of 2 or 3 cm of water (about 6% of the mean solar tide). On the other hand, if we are more interested in the maxima of the tide-raising forces themselves, or in movements of the Earth's crust which respond to them more directly than the ocean, then position relative to the equator becomes irrelevant and we should confine attention to the times of perihelion. The dates when both types of maxima occurred are considered separately below.

I restricted the computations to the years 1 to 4000 AD. Outside this range, the accepted formulae become unreliable and interest in the problem diminishes. For the times of peak tide-raising forces, the computer was asked to select the years for which the following conditions all occurred simultaneously: (a) Earth at perihelion, (closest to Sun); (b) longitude of Moon's perigee within a small angle ϵ of perihelion or of its converse (aphelion); and (c) longitude of Moon's ascending node within ϵ of perihelion or of its converse. The Moon's actual (mean) longitude was also computed at the given times, to check whether the angular limits were not violated by the time needed to adjust to the nearest appropriate conjunction with the Sun (the conjunction very near to perigee). Standard formulae, as found in the *Astronomical Ephemeris*, were used for the four relevant mean longitudes. With $\epsilon = 5^\circ$, perihelion satisfied the above conditions in only the following years: 1340, 1433, 1526, 1619, 3182, 3275, 3368 and 3461.

The appearance of the year 1433 shows that this was the type of calculation behind Macmillan's dates, but 3300 does not appear and there is no suggestion of a 1,600 yr cycle. On

the contrary, the salient features are sequences of exactly 93 yr occurring in groups of four in alternate millennia (also confirmed by tentative calculations for the first millennium bc). The 93 yr period arises because it is close to 5 times the 18.61 yr period of revolution of the Moon's nodes and 10.5 times the 8.85 yr period of perigee—condition (b) permits half periods. But, as the basic periods are strictly incommensurate, one cannot expect any exact cycle of repetition.

The configurations on most of the eight occasions above are, however, somewhat spoilt by the longitude of the Moon itself. If the Moon's 'anomaly' (its angular distance from perigee) is more than about 60° at the given instant, an adjustment of 5 to 15 d is required to define the optimum position, during which time the Sun moves by as many degrees as days. The only cases for which the Moon's anomaly and its angular distance from the Sun are less than 60° are in the years 1340 and 3182. Only in these two years does the peak tide-raising force truly occur within 5° of perihelion, perigee and a node.

Turning now to the case of peak semi-diurnal tides, the relevant computations follow a similar pattern, except that in the descriptions of conditions (a), (b) and (c), 'perihelion' is replaced by 'equinox'. (That is, I take the Sun over the equator instead of at its least distance from Earth.) Since equinoxes occur twice as often as perihelion, the conditions tend to be satisfied more frequently. The interval of 4.4 yr between passages of the longitude of perigee past the equinoxes, (condition (b) has been observed in the study of extreme low (or high) predicted sea levels². It might be thought that condition (c) should be confined to the autumnal equinox, so that the 18.61 yr 'nodal modulation' gives the constituent M_2 its greatest amplitude, but in fact when the Moon passes the equator, M_2 is in phase with K_2 , which has a correspondingly reduced amplitude, and other 'nodal modulations' are similarly self-cancelling. So both equinoxes are equally valid in condition c.

With $\epsilon = 5^\circ$, the three conditions are satisfied on 27 occasions in 1 to 4000 AD. Only those for which the Moon is within 60° of the appropriate conjunction are shown in Table 1; for reasons stated earlier. V represents the vernal and A the autumnal equinox.

TABLE 1 Most likely dates of peak tides

135A	1020V 1113V 1745A 1922A	2192A 2732V 2825V	3002V
------	----------------------------------	-------------------------	-------

This time no cyclic pattern emerges, either in Table 1 or in the complete list of 27 dates. Intervals of 93 yr occasionally appear (for example, 1020–1113 and 2732–2825) for the same reason as before, but the use of the fixed reference of the equinox instead of the slowly moving perihelion renders the 93 yr cycle less persistent.

The conditions for 1922 were particularly favourable, since the Moon was less than 1 d off 'change' (the instant when 'New Moon' commences) at the time of the equinox and the other relevant angles were also very small. Accurate computations of the lunar and solar ephemerides³ show that the peak semi-diurnal tide-raising force occurred 1922 September 21 0539 h GMT, with amplitude 1.8728 times the mean lunar amplitude (M_2) or 1.2782 times the mean 'spring' amplitude ($M_2 + S_2$). Actual ocean tides usually reach their peak a little later than the peak tidal forces, because of the peculiarities of their dynamic response. Among tide-gauge records from 1922 which are ready to hand, Brest reached a peak of $1.72 \times M_2$ range, ($1.28 \times$ mean 'spring' range) on the tide of September 22 p.m. to

September 23 a.m., while Newlyn reached $1.64 \times M_2$ range ($1.22 \times$ mean 'spring' range) on the same tide.

Dynamic response may well, of course, cause the tide at a given place to reach its ultimate peak in other years. Places with large diurnal components would again require a quite different set of conditions.

This subject has recently taken on a surprising topicality because of widespread press reports (some grossly exaggerated) of forecasts of unusually large tides for certain days in 1974. The situation is that on January 8 the Moon's perigee occurred within less than 2 h of Full Moon, while the Earth was within 5 d of perihelion. This is close to the conditions for peak tide-raising forces but the fact that the Moon's line of nodes was some 16° away from the Sun disqualifies it from my more rigorous conditions. Being some 72 d off the spring equinox, the (semi-diurnal) oceanic tides are not extraordinarily large and a glance through the tide tables of recent years confirms that equally high and low waters were forecast, for example, for 1966 and 1972. The Full Moons of February and March 1974 occur successively later than perigee, but the approach of the equinox of March 21 compensates to make the spring tides about equally high in all three months. A similar sequence occurs in July, August and September when perigee occurs near New Moon but this time the Sun is not unusually close. The year 1974 is perhaps remarkable for its number of fairly large tides but if one were to compute the occurrences of equal or greater tides in 4,000 yr, one would obtain a very long list.

I thank Mr C. R. J. Davey for calling my attention to the inconsistencies in Macmillan's account of the subject¹.

Creation of an artificial lunar atmosphere

THE tenuous nature of the lunar atmosphere is maintained by rapid loss of gases released at the lunar surface. But would such rapid loss still occur if the density of the lunar atmosphere were greatly increased from its present value? Here I seek to answer this question by evaluating quantitatively the atmospheric loss mechanisms operating in the lunar environment. One conclusion is that if the density of the lunar atmosphere is increased, a point can be reached where loss occurs so slowly that it is negligible over human time scales (that is, exponential decay lifetimes are greater than hundreds of years). So the present lunar 'vacuum' is a fragile state that should be treated carefully if it is to be preserved or could be modified if so desired.

The present lunar atmosphere has measured surface number densities of less than 10^7 cm^{-3} (refs 1–3) and a total mass of approximately 10^4 kg . As a result the entire lunar atmosphere is a collisionless exosphere in which the constituents travel along ballistic trajectories between collisions with the surface. When they are re-emitted from the surface, a fraction have sufficient thermal energy to escape from lunar gravity. The exponential lifetime against such thermal escape is about 3,000 yr for atoms of mass 20 (ref. 4). A more efficient loss mechanism, however, is operating in the lunar environment^{2,4,5}. This involves the interplanetary electric

Fig. 1 Loss rates for an oxygen (mass 16 a.m.u.) atmosphere. Molecular oxygen has a smaller thermal escape rate but dissociation would occur in the upper atmosphere. The thick atmosphere thermal loss has probably been overestimated since I have assumed the entire planetary exosphere to be isothermal. Also, exospheric heating may not occur as rapidly as indicated. At a total mass of 10^8 kg the lunar atmosphere approaches a constant rate of mass loss. Temperatures are in K.

field resulting from the motion of the solar wind. An atmospheric ion formed through photoionisation by the solar ultraviolet or by collisional ionisation by the solar wind is accelerated initially in the direction of the interplanetary electric field. Half of the atmospheric ions are thus lost into space and half are driven into the surface. The time constant for exponential decay of the atmosphere by this process is determined by the ionisation lifetime (typically 10^6 to 10^7 s). Thus, gases added to the lunar exosphere are lost within weeks to months. This rapid loss has been confirmed by observations of Lunar Module exhaust gases by the Apollo Suprathermal Ion Detector Experiment^{6,7}. There is, however, a limit to the amount of atmosphere that can be swept away by the solar wind. If the atmosphere is dense, newly formed ions of atmospheric origin load down the solar wind flow and divert it around the planet. Thermal escape may then become the dominant loss mechanism.

A quantitative evaluation of these atmospheric loss mechanisms is shown in Fig. 1 for an oxygen atmosphere. The exospheric loss rate to the solar wind was calculated assuming that the total ionisation rate was 5×10^{-6} ion per atom s^{-1} and that half of the exospheric mass was on the dayside. The limit to mass lost to the solar wind for a thick atmosphere is taken as equal to the solar wind mass flux through the lunar cross section ($\sim 30 \text{ g s}^{-1}$), since critical mass loading of the solar wind occurs if ions are added at a rate comparable to the solar wind flow⁸. Venus and Mars each lose about 10 g s^{-1} to the solar wind^{8,9}, which is 1% (Venus) and 20% (Mars) of the mass flux of the solar wind through their cross-sectional area. The thermal escape rate⁴ was calculated with 300 K as a weighted average of the lunar surface temperature. Absorption of the solar wind and ultraviolet by a thick atmosphere results in exospheric heating and more effective thermal evaporation. As the atmospheric density is increased, however, the exospheric base rises above the surface and the mass lost to thermal evaporation becomes constant. Consequently, the lifetime increases linearly as the atmospheric mass increases. It is not yet certain to what density the lunar atmosphere can be increased; this problem is being investigated.

Figure 2 shows the ultimate atmospheric masses which result from various constant gas addition rates, Q . The effect of inducing a transition from an exosphere with rapid loss to a thick atmosphere with slow loss is illustrated by considering

the result when the gas source is shut off ($Q = 0$). The thick atmosphere decays with an exponential lifetime of several hundred years whereas the thin exosphere decays in a few weeks. It is estimated that a constant addition rate of approximately 100 kg s^{-1} is required to transform the lunar exosphere into the long lived atmosphere state. Although the total atmospheric mass would increase to 10^8 kg , the surface density would still be low compared to densities in the terrestrial atmosphere.

These considerations do not include possible loss of gases to the lunar surface. Adsorption of gases such as nitrogen oxygen and carbon monoxide by the lunar soil is reversible and permanent retention (chemisorption) generally does not occur¹⁰⁻¹³. The adsorptive capacity of lunar soils is typically only 10^{-4} to 10^{-5} g of adsorbate per g of soil, and the crystalline rock is probably a factor of 10 to 100 less adsorptive¹¹. Assuming that the upper 1 mm of the entire lunar surface fully adsorbs gases with a capacity of 10^{-5} , then the total capacity is $5 \times 10^8 \text{ kg}$. This is comparable to the estimated minimum mass needed to produce a long-lived atmosphere. Consequently, surface adsorption of gases would at worst result in a slight delay in atmospheric growth but would not act as a permanent barrier.

The significance of these quantities can be evaluated by examining ways of artificially adding gases to the lunar atmosphere. Each Apollo mission deposits nearly 10^4 kg of rocket exhaust into the lunar environment⁴. Since this is much less than the 10^8 kg needed to create a long lived atmosphere, exploration at the rate of several Apollo missions per year would seem to present no lasting hazard to the lunar environment. A permanent lunar base would possibly release gas at a rate equivalent to $10^{-2} \text{ kg s}^{-1}$ per man, assuming supply traffic equal to one Apollo mission month⁻¹ per man. Therefore small lunar colonies would probably not produce a long lived atmosphere. But even modest lunar exploration is likely to release gas faster than the present natural source rate of $\sim 20 \text{ g s}^{-1}$, resulting in a lunar atmosphere in which the gases of natural origin would be only trace components. Vigorous lunar exploration and colonisation could easily result in gas release rates greater than $10^{-2} \text{ kg s}^{-1}$ per man. Proposed activities such as placing factories on the Moon to avoid pollution of the Earth's atmosphere¹⁴ need careful evaluation to avoid lasting contamination of the lunar environment.

Fig. 2 Growth curves of the lunar atmosphere for various constant gas addition rates, Q . The transition to a long lived atmosphere occurs at a total mass of 10^8 kg which requires a rate of release of gas of about 10^2 kg s^{-1} . The present lunar atmospheric mass is approximately 10^4 kg and is maintained by a natural source of $\sim 20 \text{ g s}^{-1}$. Comparable densities in the terrestrial atmosphere are indicated. ---, Decay in total mass if the gas source is shut off

If one wanted intentionally to create an artificial lunar atmosphere, gases can be obtained by heating or vaporisation of the lunar soil. Approximately 25 MW is needed to produce 1 kg s^{-1} of oxygen by soil vaporisation. An efficient mechanism for gas generation is subsurface mining with nuclear explosives. K. Ehricke (in a North American Rockwell report) estimates that a 1 kton nuclear device will form a cavern approximately 40 m in diameter from which 10^7 kg of oxygen can be recovered. Application of this technique can easily generate enough gas (10^8 kg) to drive the Moon into the long lived atmosphere state.

The desirability of intentionally increasing the density of the lunar atmosphere is highly questionable, since the primary applications of a lunar laboratory involve utilisation of the present lunar 'vacuum'¹⁵⁻¹⁷. But the artificial generation of an atmosphere can be considered as another potential method for human modification of planetary environments¹⁸⁻²¹.

Thermal emission of Saturn's rings and disk at $34 \mu\text{m}$

OBSERVATIONS from aircraft of Saturn's thermal emission do not resolve the flux component of the rings from that of the planet^{1,2}. Ground-based observations in the windows at 11 and $20 \mu\text{m}$, which resolve the rings and disk contributions, include only a small fraction of the thermal flux and are sensitive to greenhouse effects³⁻⁶. Using new filter techniques

for ground-based observations⁷, we have measured the relative thermal emission from the rings and disk of Saturn in the band from 29 to $43 \mu\text{m}$. This measurement provides an important constraint for separating the thermal properties of Saturn from those of its rings.

Ground-based photometry extending to $\sim 40 \mu\text{m}$ is possible from high altitude sites under dry weather conditions^{7,8}. The measurements between 29 and $43 \mu\text{m}$ reported here were made with the 224-cm telescope at Mauna Kea Observatory in March 1973. Additional measurements at 17 to $28 \mu\text{m}$ for normalisation purposes were recorded in September 1973. For convenience we refer to the band 29 to $43 \mu\text{m}$ (FWHM) as the $34\text{-}\mu\text{m}$ band, and the band 17 to $28 \mu\text{m}$ as the $20\text{-}\mu\text{m}$ band, although the effective wavelengths may depart significantly from these nominal values depending upon the source spectrum. In both spectral bands the ring and disk components were measured separately with a 9 arc s aperture centred on the disk and on the ansae at Cassini's division (the latter position subtended about equal areas of the A and B rings). The beam was sinusoidally chopped over a distance of 27 arc s along a direction aligned within a few degrees of Saturn's polar axis. East and West ansa readings did not differ significantly and were averaged in the final result. A check of scattered disk radiation at a polar sky position 18 arc s from the disk centre gave no measurable reading.

The ratio of the signals obtained for the ring and disk positions was 0.39 ± 0.05 in the $34 \mu\text{m}$ band and 0.49 ± 0.02

FIG. 1 Measured sky emission, compared with theoretical atmosphere transmission. *b*, Sky emission spectrum ($\sim 2 \text{ cm}^{-1}$ resolution) measured with the $34\text{-}\mu\text{m}$ filter and detector system attached to an interferometer. The saturated portions of the sky emission spectrum were used to establish the dashed baseline. The dashed line spectrum is computed from laboratory blackbody measurements, at a lower resolution, and shows the emission which would be observed on the same scale from a 270 K blackbody with an emissivity of 0.2 and the same filter system. *a*, Corresponding spectral features in a theoretical atmosphere transmission spectrum which has been computed by V. Kunde for 0.5 mm of atmospheric water content and a spectral resolution of 5 cm^{-1} .

in the 20 μm band, where the errors represent one standard deviation of the mean. To correct the 34- μm measurement for instrumental effects, we compared the 20- μm result to the transmission-weighted spectral ratio for the rings and disk of 0.82 ± 0.02 determined from Murphy's 20- μm band brightness temperatures⁶. We assumed 1 mm of precipitable water vapour for determining the transmission-weighting function. This value for the 20- μm observations was inferred from daytime water vapour observations. The difference between the present ratio 0.49 and 0.82 from Murphy's data gives the composite correction for aperture filling factors (geometrically ~ 0.7 for the ring position), diffraction of ring flux out of the aperture and different source 'dwell times' with our sinusoidal chopping for the ring and disk readings. From this 20- μm calibration procedure, we deduce that the transmission-weighted specific intensity ratio of the rings (A and B) to the disk is 0.67 ± 0.13 in the 34- μm band. This allows for an additional 3% diffraction loss computed for the ring signal at this longer wavelength. We have assumed that systematic errors due to centering differences are small.

The interpretation of our results does not depend on knowing the absolute transmission and depends on the relative transmission spectrum only in so far as the ring and disk spectra differ. Because of the collision-induced H_2 opacity source at 28 μm , model atmosphere calculations depart from that of a blackbody in this spectral region⁹. Figure 1 compares a zenith sky emission spectrum, obtained during dry atmospheric conditions in March, with the theoretical transmission for 0.5 mm precipitable water vapour content. We divided the sky emission spectrum of Fig. 1b, which also incorporates the filter transmission properties, by a 270 K Planck spectrum. This result approximates the relative atmospheric-system transmission for weighting model spectra of the rings and disk. Saturn was observed at 34 μm through less than 1.2 air masses and with atmospheric conditions comparable to those for the spectrum shown in Fig. 1b.

We can use the 34- μm observations to derive a model effective temperature for the planet by assuming: (i) that the A and B rings exhibit the same average brightness temperature of 91 ± 3 K in the 34- μm band as in the 20- μm band⁶; and (ii) that Trafton's model atmosphere calculations represent the planetary spectrum⁹. We obtain a model effective temperature of 103 ± 6 K by an extrapolation of Trafton's spectrum for a 100 K model with zero helium abundance. This result compares to a blackbody brightness temperature of 99 ± 6 K for the planet in our 34- μm bandpass. Present models of the ring involving large particles lend some support to an assumption of a fairly constant ring brightness temperature between 17 and 43 μm (ref. 10). The lower ring temperature of 83 K observed at 12 μm in 1969 (ref. 4) can be explained by assuming the ring brightness temperature increases as the Saturnicentric declination of the sun increases⁶.

We can also use aircraft measurements of the total system flux to estimate ring and disk temperatures. Armstrong *et al.*¹ report a composite brightness temperature of 89 ± 4 K in the band 30 to 45 μm . Their quoted error does not allow for the uncertainty in absolute flux calibration. The resolution of this measurement into ring and disk components, consistent with our measurement of their relative emission in approximately the same bandpass, yields an average blackbody brightness temperature of ~ 86 K for the rings and a model effective temperature of ~ 96 K for the planet. These temperatures do not differ significantly from those derived above if we allow for the absolute flux calibration uncertainty in the aircraft measurement and differences in bandpass characteristics.

The results reported here support previous suggestions of a large internal heat source for Saturn². For example, using Walker's bolometric albedo¹¹ of 0.61, we calculate a solar equilibrium temperature of 71 K. A model effective temperature

of 96 to 103 K implies an internal heat source of 2.3 to 3.4 times the solar insolation.

We acknowledge discussions with Professor W. M. Sinton, and Drs L. M. Trafton, V. Kunde, and L. J. Caroff; and observational assistance by Messrs D. F. Lester, M. W. Cromar, and the Mauna Kea staff. Reflection from a transversely moving mirror

ALTHOUGH there have been many experiments which demonstrate the first order Doppler effect in the reflection of electromagnetic waves from a mirror with a component of radial motion, there has not yet been a precise determination of the frequency of light reflected from a transversely moving mirror. There is some confusion about whether light reflected from a mirror moving transversely to an incident beam should be reflected at a frequency which is different from that of the beam, because of a relativistic (second order Doppler) effect^{1,2}. Any frequency shift would be extremely small, and there are severe experimental difficulties in attempting to observe a shift of magnitude equal to or less than that associated with the transverse Doppler effect. The experiment described here was designed to overcome these difficulties and to investigate the possibility of frequency shifts of a smaller magnitude than that which would correspond to the second order Doppler shifts associated with transversely moving emitters³. The overall accuracy of the experiment is better than one part in 10^{16} .

A rotating mirror, supported by an air bearing, is in one arm of a Michelson interferometer. The other arm has a

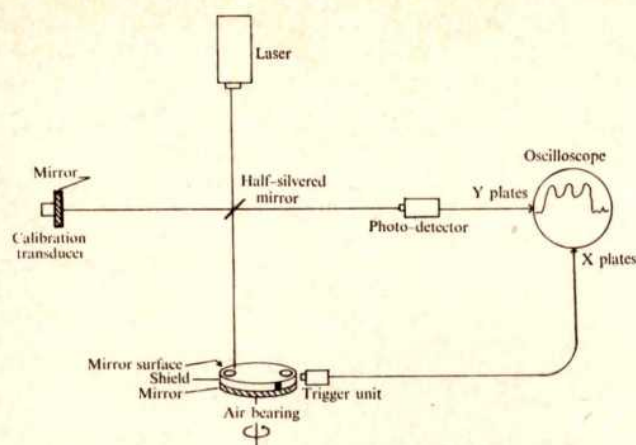

FIG. 1 The arrangement for synchronising the display from a Michelson interferometer in order to investigate any frequency shift in light reflected from a transversely moving surface.

mirror which can be moved in the direction of the reference light beam by a crystal transducer. This mirror, when moved, demonstrates that the equipment is functioning correctly, by changing the position of the fringes displayed on the oscilloscope screen.

The fringes are monitored by the photodetector, which delivers an output to the 'Y' plates of an oscilloscope. The oscilloscope time-base is triggered at the same frequency as the rotation of the mirror. Thus each particular point on the mirror corresponds to one particular part along the 'X' axis of the display. This removes the effects of variations in the mirror profile and of periodic vibrations of the rotating mirror which are related to the frequency of rotation.

Any relativistic frequency shift produced by the transverse motion should cause the two beams to beat together and thus the pattern displayed on the oscilloscope should undulate at each value of X. The control mirror, which may be considered as introducing a first order Doppler effect, shows this effect quite clearly. Calculations show that at the transverse speeds of $5\text{--}20\text{ m s}^{-1}$ used in the experiment, beat frequencies of the order of one beat per second to one beat in twelve seconds would be produced by a mechanism of the magnitude of the second order Doppler effect for a transversely moving emitter. Observation for 10 times the associated beat period showed no evidence of any shift in the position of the fringes in the display. The apparatus is being modified and we hope to improve the accuracy of the experiment and then to publish the results in greater detail.

An explanation of why no frequency shift occurs has been produced by using standard transforms of direction cosines of electromagnetic waves. The light is received at the mirror surface at an angle of approach and shifted to the blue. The blue light is then emitted specularly at the mirror, making an equal and opposite angle to the normal to the mirror surface. This reflected beam is received back in the laboratory at normal incidence and restored once more to its original colour. Einstein's equation⁴ is a restricted analysis of the complete phenomenon. It is restricted to motions in the direction of the normal to the mirror surface. Reflection by a transversely moving mirror is the other special case.

Discovery of three earthquake faults in Iran

An earthquake fault is a ground fracture formed in association with a shallow earthquake, usually by reactivation of a pre-existing geological fault. It can provide information about both the mechanism of seismic energy release during an earthquake and the accompanying regional strains. Until now only two such faults which have been adequately documented are known in Iran. These are associated with the Buyin Zara (1962) and the Dasht-e Bayaz (1968) earthquakes¹⁻³. The Torud (1953) and the Ashkhabad (1948) earthquake^{4,5} (the latter in the USSR, just north of the Iranian frontier), were probably also accompanied by faulting, but complete documentation is lacking. Here, we describe three additional earthquake faults found during recent seismotectonic field studies in Iran. The earthquakes involved were at Selakhor (1909), Baghan-Germab (1929) and Salmas (1930). Figure 1 shows the location of the three faults and of the other known and probable faults already mentioned.

The Selakhor earthquake occurred at 02 h 48 min 18 s GMT on January 23, 1909 in the upper Ab-i Diz valley in the Selakhor District of the Zagros mountains (south-western Iran). The body wave magnitude of the event was 7.4 (ref. 6). Maximum destruction was confined to the south-eastern part of the valley, between the village of Zargina and the small town of Dorud, with the preliminary macroseismic epicentre (taken as the centre of the area of maximum destruction) located at about $33.5^{\circ}\text{N } 49.0^{\circ}\text{E}$ (Fig. 2).

Contemporary descriptions of ground deformation⁷ suggest that faulting occurred during the earthquake. The eroded fault scarp is clearly visible now on the ground and on aerial photographs, and can be followed in a 135° direction from Kalangona to Dorud and Sarawand (Fig. 2). In the alluvium of the Ab-i Diz Valley it appears as a rectilinear

FIG. 1 Location of known earthquake faults in Iran. Dates indicate year of earthquake associated with faulting, with double frame for the three faults studied here. Question mark for cases in which documentation is incomplete.

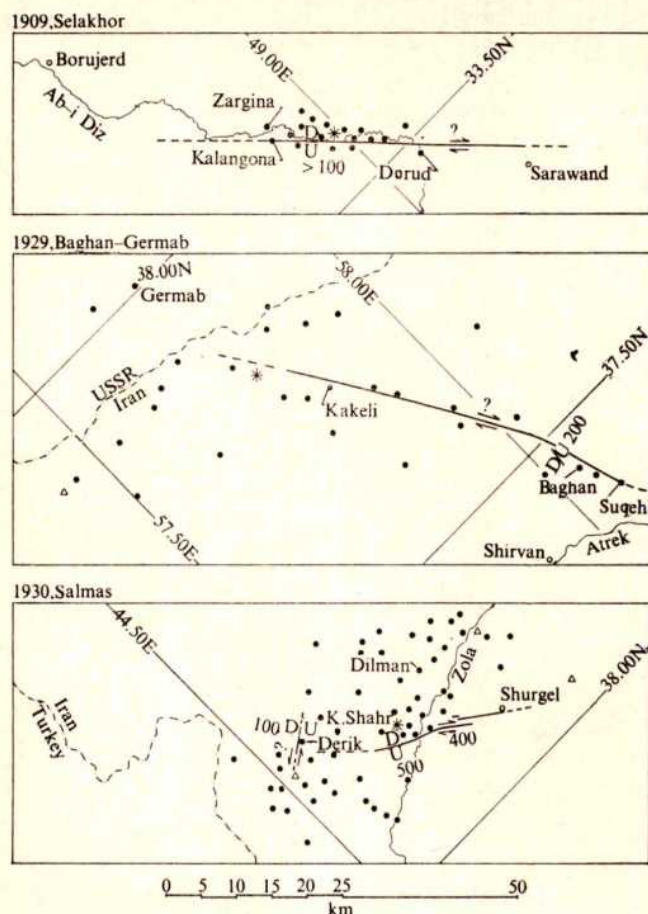

FIG. 2 Earthquake fault trace and damage distribution. Black line indicates fault trace, dashed where uncertain. Vertical fault displacements during the earthquake are shown by U (up) and D (down) and horizontal displacements by double arrow. Numbers are displacements in cm, with question mark where sense of displacement is known but not the amount. ●, Villages totally destroyed or very severely damaged. *, Approximate centre of area of maximum destruction, taken as macroseismic epicentre. △, New thermal spring created, or existing spring modified, by the earthquake.

topographical step along which the north-eastern side is downthrown by at least 1 m. Horizontal displacements have so far not been determined. South-east of Dorud, the earthquake fault enters the mountain range where it can be seen to coincide with a well marked pre-existing geological fault. The total length of the 1909 fault scarp exceeds 40 km.

Detailed geological mapping has shown that the earthquake fault was formed by reactivation of a much larger NW-SE structure, the Main Recent Fault. This is a major wrench fault extending over 1,700 km from eastern Anatolia to the Gulf of Oman⁸. It is later than, and quite distinct from, the post-Pliocene Main Thrust^{9,10} which is considered to mark the northeastern edge of the Arabian Plate¹¹ (Fig. 1). The Main Recent Fault probably results from the latest NNE motion of the Arabian Plate with respect to Central Iran, and is at present seismic to the north-west of the 1909 epicentral region, but in the south-east no data has yet been found to establish its activity.

The Baghan-Germab earthquake occurred at 15 h 37 min 36 s GMT on May 1, 1929 in the Kopet Dag mountains (north-eastern Iran) with a magnitude of 7.1 (ref. 6). Maximum destruction and ground deformation were observed along a NNW-SSE zone between Baghan (Iran) and Germab (USSR), with the preliminary macroseismic epicentre located at 37.8°N 57.8°E (Fig. 2).

Surface faulting over a length of about 50 km was associated with the earthquake, extending across the fold

trend in a 150° direction from Suqeh to the vicinity of the Soviet border (Fig. 2). It was mapped along two sections, at Baghan and at Kakeli, and the overall trace was drawn on the basis of aerial photographs together with information from contemporary accounts¹² and interviews with survivors of the catastrophe. Today, the eroded scarp is in places up to 2 m high, with the north-eastern side uplifted (Baghan region). There is also some indication of dextral strike-slip movement, but more field work is required to obtain accurate measurements of this displacement. The linearity of the earthquake fault trace through varying topography indicates that it is probably vertical at depth.

The 1929 earthquake fault resulted from reactivation of a post-Pliocene fault zone which extends from Bakharden (USSR) to Quchan (Iran) (Fig. 1). This zone forms part of a fault system which dissects the late Alpine folds of the Kopet Dag and consists of NNW dextral and NE sinistral strike-slip faults and minor E-W thrusts. This system is consistent with a NNE-SSW direction of tectonic compression. Quaternary horizontal displacements on some of the individual faults amount to several kilometres¹³, and several have been shown to be active¹⁴. In the north, the Bakharden-Quchan fault zone bends into the Main (Kopet Dag) Fault which marks the southern edge of the Turan Plate. In the south the fault zone crosses the Atrak River near Quchan, which has been devastated at least three times by earthquakes during the 19th century.

The Salmas earthquake occurred in west Azarbaijan (north-western Iran) on May 6, 1930, almost exactly one year after the Baghan-Germab earthquake. It was preceded on the same morning by a moderately strong foreshock. The main shock, which occurred at 22 h 34 min 27 s GMT, had a magnitude of 7.2 (ref. 6) and caused extensive destruction throughout the Salmas valley and the mountains in the south and west near the Turkish frontier (Fig. 2). The preliminary macroseismic epicentre was located at about 38.2°N 44.7°E.

The earthquake fault scarp can be seen over about 20 km between Shurgel and the region west of Kohneh Shahr at the southern edge of the Salmas valley (Fig. 2). Its average direction is 120° and maximum displacements during the earthquake were about 4 m dextral and 5 m

FIG. 3 Salmas earthquake, 1930: Fault scarp south of Kohneh Shahr. The scarp crosses an early Christian cemetery (from bottom right of photograph to background). The ground, which was originally level, dropped by a maximum of 5 m north of the fault (left of photo). The two figures at foot of scarp provide a scale.

downwards on the north-eastern side (Fig. 3). Survivors of the earthquake describe the fault as extending another 10 km to the north-west, but no trace of this scarp can now be seen. At Derik, a separate earthquake fault downthrown about 1 m to the north-west extends for about 3 km through metamorphic rock in a 55° direction. The pattern formed by the location of Quaternary and active travertine springs suggests that the corresponding geological fault has a sinistral horizontal component. At the south-western end of the Derik fault a thermal spring ceased at the moment of the earthquake, and a new one appeared about 1 km further south-west in the same alignment. Other thermal springs appeared, and an existing one at the south-eastern end of the main fault segment increased its flow.

The sense of vertical displacement along the main earthquake fault, and observations of waterlogging in the fields of the Salmas valley, show that the valley subsided during the earthquake. The importance of the dextral displacements, however, and the movement along the Derik fault, indicate a more complex tectonic situation which may be interpreted in terms of a N-S or a NNE-SSW compression. The structure of this part of the country, which is now being mapped by the Geological Survey of Iran, has not yet been studied and it can only be noted at this stage that the general NW direction of the earthquake fault is also that of the major regional active faults: one passing through Tabriz and Maku in the north, the Main Recent Fault (Zagros) in the south, and the North Anatolian Fault further west, in Turkey.

The small number of earthquake faults known in Iran is surprising in view of the high seismicity of the country and the presence of faults known to be active¹⁵. This is possibly because aseismic fault activity (fault creep) plays a large part in the process of tectonic strain release. There is also a lack of adequate macroseismic documentation. In this respect it is interesting to note that four out of the five earthquake faults known with certainty (Fig. 1) were over 40 km long, and that all were associated with events of magnitude greater than seven. It seems probable that, as in other seismic countries^{16,17}, shorter surface breaks have occurred in Iran during earthquakes of smaller magnitudes, but that these earthquake faults have passed unreported or even, in desert areas, unnoticed. The three earthquakes summarised here emphasise the danger, common in Middle Eastern seismotectonic research, of drawing conclusions on the only available basis of instrumental epicentre data covering the last one or two decades. With such data the regions of the 1909, 1929 and 1930 earthquakes seem to be relatively quiescent, and the activity of the associated faults is not noticed.

It would be premature at this stage to integrate the new information presented here with existing knowledge on the tectonics of Iran. The common characteristic of the three earthquake faults should, however, be kept in mind during future field studies. In all three cases, fault directions and displacements are most easily interpreted as indicating present day NNE-SSW compression. This manifests itself in the regions of contact between Central Iran and the adjoining plates—the Arabian Plate in the south-west (1909 earthquake) and the Turan Plate in the north-east (1929 earthquake), as well as in the slightly more internal region of West Azarbaijan (1930 earthquake). A predominantly NNE direction of plate motion has been postulated for Arabia on the basis of fault plane solutions for recent earthquakes¹⁸, but field evidence is so far lacking. It remains to be seen whether shallow earthquakes in more central parts of Iran may be similarly interpreted.

Detailed reports are in preparation by the authors for the 1909 earthquake (J. S. T., J. B.), the 1929 earthquake (J. S. T.) and the 1930 earthquake (J. S. T., M. B.). We thank N. Khadem, Managing Director of the Geological

Survey of Iran. A grant from the Natural Environment Research Council supported part of the work.

Geology and volcanic history of Pico Island Volcano, Azores

THE Azores Islands formed as a result of volcanism along a conservative plate margin¹. The volcanism and seismicity of the archipelago have been described² together with chemical analyses of lavas from many of the islands³.

The Mid-Atlantic ridge crest isolates the most western islands, Flores and Corvo, from the rest of the archipelago. The semismicity of the ridge branches eastwards along a more subdued ridge; the Azores-Gibraltar-Rise. The latter is primarily a strike-slip fault zone with tensional characteristics and associated volcanism in the Azores region, and a compressional zone in the region immediately west of the Straits of Gibraltar^{4,5,6}.

A secondary spreading ridge has formed in the Azores region, resulting from a combination of a different spreading rate north and south of the archipelago and a change in crustal spreading direction⁷. The secondary spreading centre is a graben known as the Terceira Rift⁸, within which three of the major Azorean volcanoes (Graciosa, Terceira and S. Miguel) have formed.

The earliest volcanism occurred in the extreme east of the island group, where basalt lava flows are exposed beneath limestones palaeontologically dated as Middle Miocene⁹. Potassium-argon dates have not yielded ages greater than 4 m.y. for lavas on Santa Maria Island and on the

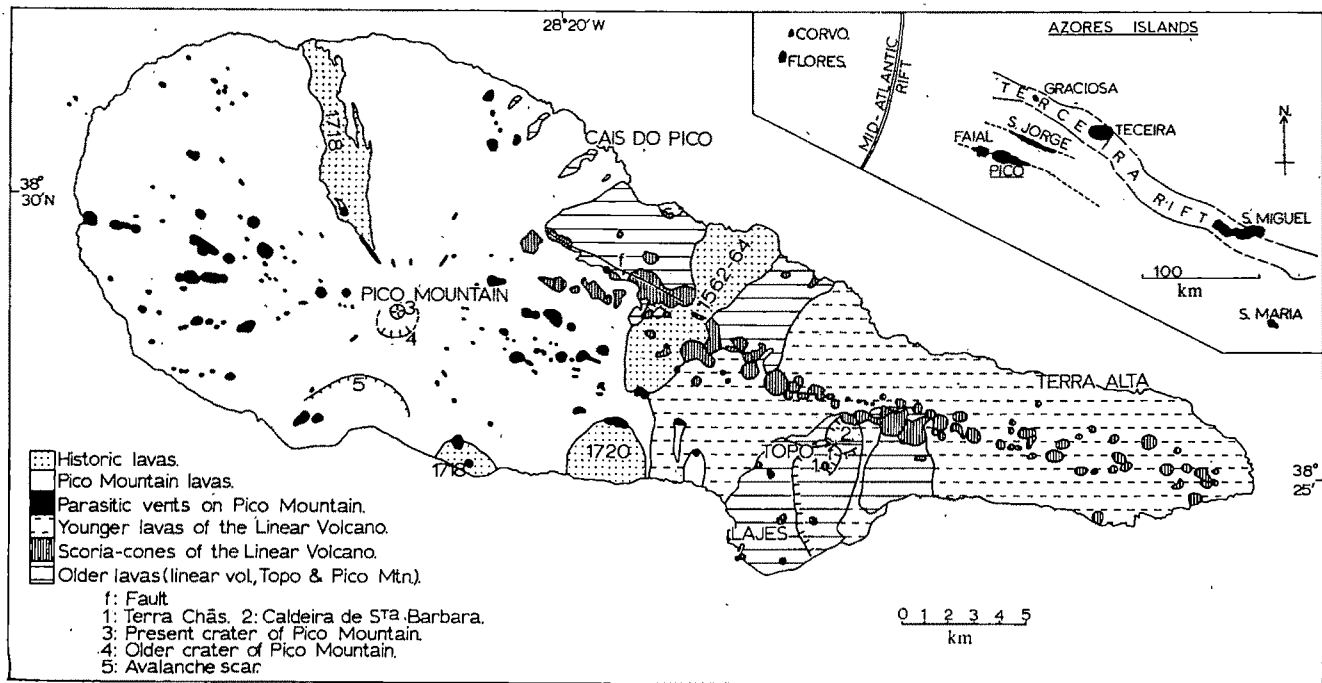

FIG. 1 Geological map of Pico Island Volcano.

extreme east of Sao Miguel^{10,11}. The latest volcanism occurred in the islands of the central group, of which Pico is a member.

Pico Island seems to be the youngest island in the Azores and is covered by many recent basaltic lava flows. Eruptions were recorded in 1562–64 and 1718–20. The island has been mapped by the Portuguese Geological Survey¹².

There is a central volcano, Pico Mountain (2,351 m), in the west and a linear volcano (1,076 m) dominates the eastern region (Fig. 1). The island is 46 km long and has a maximum width of 16 km. The volcanoes rise 3,500 m from the sea-floor and lie on a linear submarine ridge trending parallel to the Terceira Rift (Fig. 1, inset), which also includes the adjacent island of Faial.

The flanks of Pico Mountain are covered with recent lava flows erupted from radially aligned parasitic fissures. The latest activity comprises flank eruptions rather than eruptions from the central cone. The cone rises steeply above an altitude of 1,200 m with slopes up to 40°. Below this altitude, however, the slopes are seldom steeper than 8–10°. Probable gravity sliding on the steep flanks of the mountain has created a large avalanche scar (Fig. 1) on the south slopes. The slopes of Pico Mountain are composed of pahoehoe lavas derived directly from the summit crater (500 m diameter), which has since become filled almost completely by similar lavas. Fumaroles with temperatures of up to 60° C occur on the flanks of a lava cone which has formed in the north-eastern region of the crater.

The construction of the steep sided cone of Pico Mountain has probably resulted from repeated eruption, at very low rates of effusion, of pahoehoe lavas with little associated tephra, giving rise to highly compound lavas such as those exposed in the summit crater and at the foot of the mountain¹³. The flank lavas include both pahoehoe and aa flows.

The lavas of Pico Mountain contain phenocrysts of olvine and augite, in some cases with plagioclase. Crystal settling has occurred in many pahoehoe flows of ankaramiti nature, involving the accumulation of large olivine and augite phenocrysts in the lower part of a flow. Radiating plagioclase glomero-groups characterise the pahoehoe lavas of the steep sided cone. The historic Santa Luzia flow (1718), north-west of the mountain, (Fig. 1) also contains phenocrysts of hornblende, magnetite and apatite.

The Linear Volcano is offset to the north relative to Pico

Mountain. It has evolved by repeated fissure eruptions along WNW trending fissures. Young lava flows occur along the entire 30 km length, except in the extreme north-west.

The Topo Volcano is situated halfway along the Linear Volcano, slightly to the south of its main axis (Fig. 1). It is controlled by NE–SW trending fissures. Evidence suggests, however, that it has evolved as a volcano transitional between a linear and a central volcano. It is surrounded by the younger lavas of the Linear Volcano and it conveniently divides the latter into a western and an eastern Linear Volcano. No young lavas occur on the Topo Volcano.

The western Linear Volcano is divided equally into an older north-western region characterised by eroded scoria-cones together with recent fault scarps, and an eastern region dominated by young scoria-cones situated along a narrow fissure zone (Fig. 1).

The eastern Linear Volcano is also dominated by young scoria-cones, but older cones, partially buried by the younger lava flows, also occur. High cliffs which are mostly degraded,

FIG. 2 Alkalies: silica diagram for Pico rocks: ●, lavas of Pico Mountain central volcano; ○, lavas of 1718 and 1720 (Pico Mountain volcano); +, lavas of the Linear Volcano and Topo. Dashed lines divide alkali basalts from tholeiites: a, from Macdonald (1968); b, from Irvine and Baragar (1971).

such as Terra Alta, occur on both the north and south sides of this narrowest zone of the island (Fig. 1).

The younger lavas of the Linear Volcano seem to be penecontemporaneous with those of Pico Mountain.

The Topo Volcano had an old summit crater which subsequently became filled in by thick pahoehoe lavas. These may have formed a lava lake. The original crater region has been modified by caldera collapse of the 'trap door' type¹⁴ with arcuate scraps only partially enclosing a caldera, for example, the Terras Chas Depression and the Caldeira de Santa Barbara (Fig. 1). Parasitic vents and fault scraps occur to the south-west of the collapse region, and thin dykes together with some buried scoria-cones are exposed in the cliffs along the south coast.

Early in its history the Topo Volcano probably resembled the shield volcanoes of the western Galapagos Islands¹⁵ but the morphology has been modified by the caldera collapse. Only four lavas seem to postdate this event. The oldest lavas of the adjacent Linear Volcano postdate all but the latest Topo lavas.

The oldest lavas on Pico occur in the north-western region of the Linear Volcano, and on the Topo Volcano, and in both cases the lava flows are covered by ash and/or soil. Scoria-cones are considerably eroded. The oldest lavas are exposed at the foot of the high cliffs along the south coast of the Topo Volcano. Similarities between the two areas suggest that they are probably of the same age.

The lavas of the Linear Volcano are dominantly aa flows. There are very few pahoehoe lavas, although an extensive flow was erupted in the period 1562-64, from the older, western region (Fig. 1). The majority of the lavas contain phenocrysts of olivine, augite and plagioclase but older lavas may contain only olivine phenocrysts. Many of the Topo lavas are similar to those of Pico Mountain, and spectacular crystal settling, involving the accumulation of olivine and augite phenocrysts, characterises many of the pahoehoe lavas. This phenomenon is also present in the thick pahoehoe lavas which fill the old, pre-caldera, summit crater referred to already. Less porphyritic aa flows are common together with aphyric lava flows which are more commonly associated with the Topo Volcano. There are also plagioclase rich basalts which resemble those on the steep sided cone of Pico Mountain. Biotite occurs as a rare accessory mineral in some Topo lavas.

Figure 2 indicates the alkaline nature of the analysed lavas of Pico. Some hypersthene normative lavas occur and they plot on the boundary between tholeiites and alkali basalts^{16,17}. The most highly differentiated lava is a single flow of benmoreite erupted on the northwestern flanks of Pico Mountain in 1718. This is part of a lava series erupted in 1718 and 1720, which ranges in composition from olivine basalt (hypersthene normative) to hawaiiite and then to benmoreite.

Few differentiated lavas occur on Pico Mountain, and there is only very slight differentiation in the older lavas of the Linear Volcano and Topo. The younger lavas (Fig. 1) of the Linear Volcano are interpreted as a differentiated series akin to that mantling the older 'oceanite' series on Reunion Island (Indian Ocean)¹⁸. The Pico differentiated series ranges from plagioclase basalts to hawaiiite and includes two flows transitional to mugearite.

Heteromolecular clusters of H₂O, SO₂, CO₂, CO and NO

HOMOGENEOUS clusters of gas molecules in isentropically expanding jets, first observed in 1961^{1,2}, have been the subject of several experimental studies³⁻⁷. Mixed or heteromolecular clusters have also been observed in mixtures of two or more gases expanded from a high pressure reservoir. Leckenby *et al.*⁸ have identified the species Ar·CO₂, Ar·(CO₂)₂ and larger clusters, and N₂·O₂, SF₆·(CO₂)₂ and SF₆·CO₂·Ar. Milne *et al.*⁹ have observed mixed H₂O-Ar clusters and the heteromolecular dimers O₂·H₂O and NO·H₂O.

We observed mixed clusters of the type SO₂·(H₂O)_n, *n* = 1-6, of the same order of magnitude as pure water clusters when 2 mmHg of SO₂ were added to 1,500 mmHg nitrogen, saturated with water of room temperature, and expanded through an orifice of 0.0386 cm. The possible implications of the homogeneous formation of such hydrated cluster species to upper atmospheric chemistry¹⁰ and aerosol formation¹¹, led to a series of experiments with a water-saturated nitrogen carrier which was seeded with trace gas species

TABLE 1 Heteromolecular clusters observed in fully expanded jets*

Species	<i>n</i>	Concentration in nitrogen
SO ₂ (H ₂ O) _n	1-5	0.5% SO ₂
CO ₂ (H ₂ O) _n	1-5	5% CO ₂
NO(H ₂ O) _n	1-6	1% NO
H ₂ O(SO ₂) _n	1,2	0.5% SO ₂
(CO ₂) ₂ (H ₂ O) _n	1,2	5% CO ₂
(NO) ₂ H ₂ O	-	0.5% NO, 0.25% SO ₂
NO·SO ₂ ·(H ₂ O) _n	1-3	0.5% NO, 0.25% SO ₂
CO ₂ ·SO ₂ ·H ₂ O	-	2.5% CO ₂ , 0.25% SO ₂
NO(SO ₂) _n	1,2	0.5% NO, 0.15% SO ₂
NO(CO ₂) _n	1,2	0.5% NO, 2.5% CO ₂
CO ₂ (NO) _n	1,2	2.5% CO ₂ , 0.5% NO
SO ₂ (CO ₂) _n	1,2	0.25% SO ₂ , 2.5% CO ₂
CO(CO ₂) _n	1-3	0.5% CO, 2.5% CO ₂ †

* Total source pressure, *P*₀ = 2,000 mmHg. Orifice diameter, *d* = 0.0343 cm. The first eight experiments were carried out with nitrogen saturated with water of room temperature. The remainder were conducted with dry nitrogen. The species N₂·H₂O, N₂·SO₂, N₂·(SO₂)₂, N₂·CO₂, and N N₂·NO were also observed mainly as a result of the large amount of nitrogen present.

† Under the present conditions CO did not cluster appreciably with any species except CO₂.

Fig. 1 Heteromolecular clusters observed in a fully expanded jet composed of 10% H_2O , 2.5% CO_2 and 0.25% SO_2 in nitrogen. The $\text{SO}_2^+(\text{H}_2\text{O})_n$ and the $[\text{CO}_2(\text{H}_2\text{O})_n]^+$ series are connected by curves for convenience.

which are known to exist in the atmosphere and in the exhausts of jet aircraft.

The supersonic molecular beam apparatus consists essentially of a three-stage differentially and cryogenically pumped vacuum system^{5,6}. Gases and/or vapours are admitted through a sonic orifice at the end of a source probe, and the beam is formed by a helium-cooled skimmer (20° K) and then further collimated. Beam species were detected with a quadrupole mass spectrometer after mechanical beam chopping and subsequent phase-sensitive signal processing with a lock-in amplifier. For some of the latest experiments the mass spectrometer was controlled by a minicomputer and the ion signals were digitised.

Fig. 2 Heteromolecular clusters observed in a fully expanded jet composed of 10% H_2O , 0.5% NO and 0.25% SO_2 in nitrogen. The $\text{NO}^+(\text{H}_2\text{O})_n$ and the $\text{NO}^+\text{SO}_2(\text{H}_2\text{O})_n$ series are connected by curves for convenience. The $\text{SO}_2^+(\text{H}_2\text{O})_n$ series was also present in this expansion but it is not shown here in order to simplify the spectrum. It is of approximately the same magnitude as in Fig. 1.

Table 1 summarises the experimental conditions and the mixed cluster species observed. Figures 1 and 2 present

sample mass spectra to give an indication of the relative magnitudes of the ion signals. The total source pressure and orifice diameter for both cases are 2,000 mmHg and 0.0343 cm respectively. Only those peaks directly related to the heteromolecular clusters are shown, with the water cluster ion series (that is, $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$) included for comparison. The ionising electron energy was 90 V. The species actually detected were ions produced in the mass spectrometer ion source. The ionisation occurred, however, in the free molecular flow regime after all collisions had ceased and, therefore, the formation of the heteromolecular clusters was completely homogeneous. Ion-molecule reactions can be excluded because of the low pressure in the mass spectrometer ion source (about 10^{-8} mmHg) and because the observed signals were in phase with the beam chopper. A more extensive analysis of the results will be published elsewhere.

Species similar to those in Table 1 have been heterogeneously generated by subjecting low pressure gas mixtures (1–4 mmHg) to an electrical discharge and allowing them to react in a field-free reaction cell¹². In this manner the following cluster ions were observed mass spectrometrically:

and

Pending further investigation, we think that the observed mixed cluster signals are mostly virgin species formed through a simple gas kinetic mechanism, rather than from complex fragmentation of a condensed bulk phase on electron impact in the ion source of the mass spectrometer. Although the low temperatures attained in the nitrogen expansion are certainly sufficient to condense water, thus raising the possibility of some fragmentation of the bulk phase, there is some experimental¹³ and theoretical¹⁴ evidence to suggest that this is secondary to other effects. Also, in a recent experimental CO_2 condensation study, massive fragmentation was presumed absent because of the agreement between the observed and predicted dependence of cluster concentrations on source pressure and orifice diameter¹⁵.

The formation of the heteromolecular dimer probably is the rate-controlling step in the growth of mixed clusters. The dimer must be formed by a termolecular collision and higher clusters then grow by the successive bimolecular addition of monomers. A simple gas kinetic model with termolecular dimer formation and bimolecular destruction seems to be adequate to predict dimer concentrations in expanding jets^{5,15}. The surprising persistence of the species (Table 1), despite the relatively low concentrations of the apparent species in nitrogen, can only be explained by postulating strong affinity, with nitrogen serving as the third body in the dimer formation mechanism.

The results presented here have established the existence and identity of mixed clusters of H_2O , SO_2 , CO_2 , NO and CO formed during homogeneous nucleation processes in an isentropic expansion from the gas phase. There are numerous observations of the homogeneous nucleation of water vapour which has been appreciably enhanced by the presence of foreign gas molecules¹⁶⁻¹⁸. Clathrate structures of water molecules around foreign gas molecules, particularly those found as trace contaminants in the atmosphere, and most notably, in the present context, SO_2 and CO_2 may be important in aerosol physics, and furthermore, favourable conditions for the production of water clathrates are known to be present in the exhausts of jet aircraft⁹.

The mass spectra data acquisition was performed principally by Mr A. B. Bailey, ARO Inc., Arnold Engineering Development Center, Tennessee. This work was jointly sponsored by the United States Air Force and the Climatic Impact

Assessment Program, Office of the Secretary, United States Department of Transportation.

Non-linearity of hydrogen bonds in molecular crystals

In recent studies of the non-linearity of hydrogen bonds^{1,2}, histograms have been shown of the O-H ... O angles, ψ . The distributions reflect the energy dependence of the hydro-

FIG. 1 Cone of opening angle ($360^\circ - 2\psi$) illustrating the number of possible hydrogen-bond configurations with O-H ... O angle, ψ .

gen bond on the angle ψ . In such distributions maxima are found at values of ψ approximately 15° from the linear configuration. Model calculations on water dimer interactions³ indicate, however, that the configuration of minimum energy involves a linear hydrogen bond.

Before angle distributions of the hydrogen bond as observed in crystal structures, are compared with results of theoretical calculations on non-linearity in simple hydrogen bond models, experimentally determined hydrogen bond angle frequencies should be properly adjusted. This is because the sampling procedure includes a factor which complicates the correct interpretation of the histograms. This factor, which is of a geometric nature, seriously influences the statistics and has not been taken into account in other studies. This factor does not affect the observed hydrogen bond angle in any single case, but only affects the frequency distribution of the whole set of bond angles.

Assuming that the optimum hydrogen bond is linear this factor depends on ψ , because the number of possible hydrogen bond configurations at any value of ψ is proportional to $\sin \psi$. This is shown in Fig. 1, which illustrates that the acceptor oxygen atom at a certain O-H ... O angle, ψ , can select any of the positions that lie on the generator of a cone of opening angle $360^\circ - 2\psi$, with the hydrogen atom at the apex and the cone axis in line with the O-H bond.

Thus although the assumption that the energy depends on ψ indicates that the probability of a hydrogen bond with angle ψ decreases as ψ increases, in fact the probability will increase with increasing ψ because of the increase in the number of possible hydrogen bond configurations with angle ψ .

Fig. 2 Histogram of the 196 O-H...O hydrogen bond angles observed in the crystal structures listed in Table 1.

As a result of this, the maximum in the frequency distribution may be expected to occur appreciably away from 180°. In other words, conclusions about the hydrogen bond energy from angle frequency distributions can only be compared with theoretical model calculations if the spatial freedom factor is either included in the theoretical model calculations or removed from the experimental hydrogen bond angle frequency distribution.

We applied the $\sin \psi$ correction to the statistics of a series of 196 hydrogen bond angles collected from recent literature⁴⁻⁴⁸. Only one type of hydrogen bond was considered: the donor and acceptor groups were aliphatic hydroxyl groups in polyalcohols, saccharides and related compounds,

Fig. 3 The histogram from Fig. 2 after correction for the geometric $\sin \psi$ factor.

as listed in Table 1. Whereas the histogram of ψ (Fig. 2) has a maximum at 161°, the application of the $\sin \psi$ correction procedure produces a histogram (Fig. 3) that has a maximum at 180°.

Although distributions of experimental values of hydrogen bond angles at first sight suggest the opposite, we conclude that the experimental distributions, properly treated, are not inconsistent with an assumed preference for linear hydrogen bonds.

Effect of sliding on surface fatigue

IN hardened steels, sliding friction increases the tendency of loaded line contacts to suffer surface fatigue¹, which can lead to pitting. This note describes an apparatus to study this effect in point contact and gives the first results.

The most convenient test pieces for fatigue studies are bearing balls. Our device consists of a drive ball, *a*, loaded against three radially disposed idler or intermediate balls, *i*, each of which is held in a chuck running on an angular contact ball thrust bearing. A fifth ball, *d*, is driven by these three. The contact angle between all the balls is 45° (Fig. 1).

The five-ball assembly is doubled with the driven balls mounted on opposite ends of a floating shaft and thus located without bearings. On this shaft an aluminium disk, together with two d.c. coils, acts as an eddy current brake. A double-ended motor drives both the input balls. By altering the current in the brake coils various amounts of traction or slip can be achieved at the contacts. Digital tachometers on each shaft, and strain gauges connected to suitable control circuits, automatically maintain the desired value of slip or traction. The load is axially applied by deadweight.

The contact zone between any two balls is a flat circular area. Analysis shows that for this system there is no relative motion in the contact plane between the two surfaces. This device therefore undergoes pure rolling. Sliding only occurs when traction is deliberately applied by the eddy current brake. When this was not energised, no slip could be detected

FIG. 1 Schematic twin-head five-ball assembly.

within the limits of accuracy of the measuring instruments (± 1 part in 10^4).

FIG. 2 Weibull plot of results. Δ, Pure rolling; □, 0.35% slide-roll ratio.

Using balls of EN31 (diameter $\frac{5}{8}$ inch) and a synthetic diester lubricant of 7.5 cstokes at 96.8° C (210° F), a standard Weibull plot² was obtained at a maximum Hertz stress of 6 GN m⁻² (Fig. 2).

Tests were then carried out at a slide-roll ratio of 0.35% and a further plot was made. Figure 2 shows that the life decreased by 3.2 times because of this very small amount of sliding.

As no comparable apparatus exists it is not possible to see exactly how these results compare with other published data.

Tests at different contact angles³, which effectively generate different amounts of spin at the contact, have shown that on addition of small amounts of spin, the life is drastically reduced. An increase in mean spin-roll ratio from 0.168% to 0.55% reduces the life by 2.1 times. We note that the lubricant used in this case was a highly refined mineral oil quite different from the synthetic diester which we used.

The effects described here should be studied in more detail now that controlled amounts of sliding can be applied.

We thank Westland Helicopters Limited, Yeovil, for support and, especially, Squadron Leader A. Armitage of the Ministry of Defence (Procurement Executive) and Dr P. B. Macpherson for encouragement.

A full report will be published elsewhere.

Is pyrophoric iron sulphide a possible source of ignition?

THERE are many practical environments in which iron oxide, in the form of surface rust, may be exposed to atmospheres containing hydrogen sulphide at various concentrations. Gas lines, chemical plant, distillation units, crude-oil cargo and storage tanks are examples.

We wish to draw attention to the hazard that can arise in such situations because of the formation of pyrophoric iron sulphide, and the possibility that it may act as a source of ignition for inflammable vapours.

The reactions involved in the formation of iron sulphide and its subsequent oxidation on exposure to atmosphere may be represented in a simplified form as follows

Both reactions are exothermic, the ΔH° values for reactions (1) and (2), based on 2 FeS, being about -40 and -151 kcalorie (-168 and -635 kJ) respectively. If reaction (2) can proceed rapidly and with little dissipation of heat, high temperatures can be expected in the material.

We have found that the reactivity of iron sulphide depends on the type of iron oxide from which it is derived. For example, a common form of rust (α -FeOOH) yields on exposure to hydrogen sulphide a material which is particularly reactive. When exposed to air at ambient temperature, the material oxidizes so rapidly that surface glowing and sparking can be seen within seconds. If inflammable vapours come into contact with the material in this condition, the material can act as a source of ignition. We suspect that several recent minor explosions in the cargo tanks of crude-oil tankers may have been caused in this manner. This view is reinforced by the fact that we have been able to demonstrate that pyrophoric iron sulphide can form at partial pressures of hydrogen sulphide corresponding to the values encountered in the ullage regions of crude-oil cargo tanks.

It is fortuitous that in practical situations not all sulphided iron oxide is as reactive as the material described. The reactivity can be influenced by a number of factors. For instance, the progressive buildup of sulphur generated during each sulphidation/oxidation cycle can exert a 'screening' effect, resulting in reduced reactivity of the sulphide so formed. Particle geometry and the presence of occluded materials can also affect reactivity.

Although pyrophoric iron sulphide has, of course, been known for many years¹, the conditions under which it may form and the various factors that can influence its reactivity do not seem to have been fully explored. For this reason its potential danger may often be overlooked.

A fuller account will be given elsewhere.

Stereochemistry of a carbonium ion rearrangement

CONCERTED rearrangements of the carbonium ion kind ($1 \rightarrow 3$) are usually supposed to go with stereochemical inversion at the migration terminus (C^1) and retention in the migrating group (R) (ref. 1). Many chemists have recorded one or other of these results but no one has shown both in one and the same acyclic molecule, largely because

it is very difficult to find a reaction in which both centres are chiral and both survive as chiral in the product. Rigid cyclic systems do show both results at once but this is not very informative as no other outcome is conceivable in a molecule which has no opportunity for internal rotation.

We have been studying² phosphinyl rearrangements (1 , $R = \text{Ph}_2\text{PO}$), attracted by the very high yields, usually more than 95%, of single products formed in these reactions. We wanted to look at the stereochemistry at the migrating phosphorus atom, since it does not follow automatically from the carbon case that retention will be the general rule and also at carbon (C^1 in 1) since we should like evidence on the detailed mechanism of the reaction: whether, for example, the two steps shown in (1) are concerted. This kind of question is worth asking because most accounts of carbonium ion rearrangements assume that electronegative groups like Ph_2PO will not migrate easily since they cannot support the positive charge in the transition state (2).

In one of our reactions² ($4 \rightarrow 5$, $R^1 = R^2 = \text{Ph}$), a chiral migration terminus remained chiral in the product.

FIG. 1 Perspective drawing of the molecular structure of alcohol ($7a$).

FIG. 2 Perspective drawing of the molecular structure of olefin (9a).

Simply by carrying out this reaction sequence on an analogous molecule with different substituents ($R^1 = \text{Ph}$, $R^2 = \text{Me}$) on phosphorus we have been able to study the stereochemistry at both chiral centres simultaneously and to do so by unambiguous X-ray crystal structure determinations since we need to distinguish diastereoisomers and not mirror images.

We first synthesised both diastereoisomers of the alcohol (7) by reduction of the ketone (6). One alcohol was easy to make as the bulky reducing agent $\text{LiAlH}(\text{O}i\text{Bu})_2$ gave it in 90% yield. It formed chunky prisms from di-isopropyl ether-chloroform and its structure proved to be (7a) from the X-ray determination (Fig. 1). The other diastereoisomer (7b) was more difficult to make and in the end we separated a 60:40 mixture (from reduction with sodium borohydride

of the ketone (6)) by preparative t.l.c. of the tosylates. Tosylates (8a), made directly from alcohol (7a), and (8b) from the t.l.c. separation, had clearly distinct nmr spectra.

Tosylate (8a) solvolysed in formic acid at 75° C to give an olefin as the major product. This olefin (9a) was very soluble in water and in most organic solvents but formed

long thin trapezoidal prisms from dry 100–120° C petrol ether. Figure 2 shows the result of the X-ray determination of crystal structure. Both structure analyses were based on diffractometer data taken with monochromatised Cu radiation. The phase problem was solved by direct methods and at the current stage of refinement the reliability factors are $R = 0.04$ for the alcohol (7a) and $R = 0.08$ for the olefin (9a).

Some of the other diastereoisomer (9b) of the olefin is also formed in the reaction; the amount varies with time and is about 15% after ten half-lives of the tosylate. If pure olefin (9a) is dissolved in formic acid at 75° C, epimerisation to form (9b) occurs at the same rate as the formation of (9b) in the reaction mixture. So (9b) is not a product of the reaction—it is formed by epimerisation of the true product (9a). Exactly parallel results—formation of (9b) as the only product of the reaction—are found when the minor tosylate (8b) is solvolysed under the same conditions. The tosylates (8) do not epimerise under the reaction conditions.

The reaction is therefore completely stereospecific: configuration is retained in the migrating phosphorus atom and inverted at the migration terminus. This result is consistent with a concerted rearrangement: a less likely but equally valid explanation would be that tosylate leaves to give a cation and rearrangement follows more quickly than rotation of the carbon-carbon bond. Certainly the reaction must be a genuine rearrangement; there can be no question of the phosphinyl group leaving the molecule to rejoin it later at the migration terminus.

BIOLOGICAL SCIENCES

Repression of RNA transcription during the development of analgesic tolerance to morphine

SEVERAL reports suggest that RNA and protein synthesis are important for the development of morphine-induced analgesic tolerance and dependency^{1–4}. Following up these reports, we have examined the effect of chronic morphine drugging on the intracellular site of RNA synthesis—nuclear chromatin. We found that brain chromatin from rats tolerant to morphine, synthesised RNA more slowly than that from non-tolerant rats⁵. This effect was not caused by the direct

TABLE 1 Chromatin template activity during morphine-induced analgesia

Treatment	pmol of ATP incorporated*
Control	1,136 \pm 47
Morphine (10 mg kg ⁻¹)	1,088 \pm 46

* Results are reported as the mean \pm s.e. for four rats. ATP incorporation by enzyme alone (340 pmol) has been subtracted.

action of morphine and was found to be associated in the chromatin complex with a protein which is believed to regulate RNA synthesis. Since we may have identified, in part, a mechanism by which morphine-induced analgesic tolerance develops, we looked for a chronological relationship between the development of morphine-induced analgesic tolerance and the effect on brain chromatin RNA synthesis.

Male Charles River rats (80–100 g) were divided into two groups: (a) morphine-treated and (b) saline control. Half the daily dose of morphine sulphate was administered subcutaneously twice daily (0800 h and 2000 h) in 0.9% NaCl. Control animals were injected at the same time with 0.9% NaCl. The initial dose of morphine sulphate was 10 mg kg⁻¹ d⁻¹. This dose was increased progressively to 100 mg kg⁻¹ d⁻¹ on the thirteenth day so that the final doses on the first, third, sixth and thirteenth days were 10, 15, 30 and 100 mg kg⁻¹ d⁻¹, respectively. All RNA synthesis and analgesic experiments were begun at 0800 h, 12 h after the last dose of morphine.

Analgesia induced by morphine sulphate was measured by the reaction of animals to being placed on a hot plate using a modification of the method described by Johannesson and Woods⁶. Rats received neither training nor predrug trials before being treated. Twelve hours after their last morphine dose, a subcutaneous 10 mg kg⁻¹ dose of morphine sulphate was given to test and control animals. After 45 min the animals were tested for analgesia. Endpoint responses were paw licking or jumping out of the cylinder with a cut-off time of 30 s. The observer was kept unaware of the treat-

ment for each group. Analgesia was registered as a delay in response to the hot plate while animals tolerant to morphine responded very rapidly.

Nuclei were isolated from individual rat brains using the methods we described previously for pooled rat brains⁶. Chromatin was extracted from rat brain nuclei according to the procedure of Paul and Gilmour⁷, and assayed for its capacity to promote RNA synthesis in the presence of *E. coli* DNA-dependent RNA polymerase according to the methods of Chamberlin and Berg⁸. The reaction mixture (0.5 ml) contained 10 μ M of Tris-HCl (pH 7.9), 1.0 μ M MgCl₂, 3.0 μ M β -mercaptoethanol, 134 μ g of RNA polymerase, 10 μ g of chromatin from either control or morphine-treated animals and 0.1 μ M of UTP, CTP, GTP and ATP (0.1 μ Ci ¹⁴C-8-ATP, New England Nuclear Corp.). Incubation was for 10 min at 37° C. The reaction was stopped by addition of an equal volume of cold 10% trichloroacetic acid (TCA). The precipitate was collected on Millipore filters, air dried, and counted in a toluene-PPO-POPOP cocktail using scintillation spectrometry.

To determine whether the decrease in rat brain chromatin template activity might be related to morphine-induced analgesia, brain chromatin was analysed from rats which had received 10 mg kg⁻¹ of morphine sulphate subcutaneously. At 60 min (a time when all the rats were analgesic) brain chromatin was extracted and its capacity to incorporate ¹⁴C-ATP into RNA measured. Table 1 shows that brain chromatin from both control and morphine-treated rats incorporated equivalent amounts of ¹⁴C-ATP into RNA even though the morphine-treated animals were analgesic.

The development of analgesic tolerance to the morphine regimen used in these experiments is shown in Fig. 1. Rats tested 1 d after morphine treatment seemed to exhibit as much analgesia to 10 mg kg⁻¹ of morphine sulphate as saline-treated rats. Analgesic tolerance became significant at 3 d and was maximal by the sixth day.

Figure 1 also shows the development of the brain chromatin depression during the same morphine regimen. After 1 d, no significant change in chromatin template activity was noted. By the third day the template activity in the morphine-treated rats was significantly depressed and this depression was maximal by the sixth day.

To examine further the relationship of analgesic tolerance and chromatin template activity, we performed hot plate and chromatin template assays at various times after the morphine regimen was stopped. Figure 2 shows the duration of analgesic tolerance produced by the 13-d morphine sulphate regimen. Seven days after the morphine regimen was discontinued analgesic tolerance was still maximal. On the twenty-eighth day, tolerance appeared to be less, but was still significantly different from control. By the thirty-fifth day, no significant analgesic tolerance was detected.

Figure 2 also shows the duration of the chromatin depression produced by the 13-d morphine regimen. Seven days after the morphine treatment was stopped, chromatin template activity was still maximally depressed. However, by the twenty-eighth day, the template activity of the morphine-treated group had increased to the level of the controls.

Our results do not support any relationship between analgesia and brain chromatin template activity, since the chromatin depression was absent during analgesia and yet maximal during analgesic tolerance.

The onset of the depressed chromatin template activity and the onset of analgesic tolerance during chronic morphine treatment seem to be related. Both became significant by the third treatment day and were maximal by the sixth day. On the other hand, when morphine treatment was stopped the depression of template activity had disappeared by the twenty-eighth day, while analgesic tolerance was still significant and did not disappear until the thirty-fifth day after

FIG. 1 Development of morphine-induced analgesic tolerance and depression of brain chromatin template activity. Each circle (○, control; ●, morphine) is the mean response time of thirteen to twenty-five rats. Each triangle (Δ, control; ▲, morphine) is the mean template activity of three to ten rat brains. The greatest number of rats were used at days 1, 3 and 6. * Denotes values which are significantly different ($P < 0.05$) from their respective control by Student's *t* test⁹.

FIG. 2 Disappearance of morphine-induced analgesic tolerance and depression of brain chromatin template activity. Each circle (○, control; ●, morphine) represents the mean response time of ten to twenty-five rats. Each triangle (△, control; ▲, morphine) represents the mean template activity of three to eight rat brains. * Denotes values which are significantly different ($P < 0.05$) from their respective control by the Student's t test⁹.

treatment. Although chromatin template depression and analgesic tolerance did not disappear together, this does not negate a possible relationship between them. If the change in nuclear chromatin template initiates the mechanism(s) producing analgesic tolerance, then one would expect such tolerance to disappear with or after the chromatin effect.

In conclusion, we found that changes in brain chromatin template activity correlated chronologically with the onset and disappearance of morphine-induced analgesic tolerance. However, it is quite possible that the depression of chromatin template activity may be related to morphine dependency, or perhaps, it is related to both phenomena. The latter possibility seems quite possible, in light of the fundamental role of chromatin in cellular RNA synthesis and the difficulty of separating morphine-induced analgesic tolerance and dependency.

Defective rRNA synthesis in human leukaemic blast cells?

RECENT studies suggest that processing of ribosomal precursor RNA might be impaired in blast cells of acute leukaemia (AML)^{1,2}. Following incubation with ³H-methyl-methionine blast cells of human acute leukaemias partially failed to methylate the 45S and 32S ribosomal precursors¹. Using autoradiographic techniques, previous studies have also shown an increase in intranuclear RNA and decreased cytoplasmic RNA in these cells³. More recently, competitive hybridisation was performed with normal lymphocyte DNA and 35S-55S RNA fractions extracted from both acute leukaemia blast cells and normal PHA-stimulated lymphocytes. Using incubations with actinomycin D these experiments have led to the conclusion that leukaemic blast cells synthesise heterogeneous nuclear RNA molecules which are not transcribed in PHA-stimulated lymphocytes and it was also suggested—in contrast to the earlier data—that the amount of unmethylated unprocessed rRNA precursor was small in leukaemic blast cells⁴.

Studies in this laboratory have yielded highly specific ³²P-labelling of nuclear and ribosomal high molecular weight RNA using a HEPES-buffered, phosphate-free medium⁵.

FIG. 1 a, Sucrose density gradient centrifugation of nuclear RNA from acute myeloblastic leukaemia cells. The cells were labelled for 6 h in a phosphate-free medium⁵. Nuclei were isolated by homogenisation in 5% citric acid and purified by sucrose step gradients⁶. The RNA was extracted by the hot phenol-SDS-method⁷ at 65° C for 5 min. RNA (1 mg) was loaded on a 6%-45% (w/w) sucrose density gradient (Beckman Density Gradient Former) and centrifuged for 16 h at 26,000 r.p.m. (3° C, SW27 rotor). The RNA was fractionated with an ISCO Model 640 Density Gradient Fractionator and aliquots of 20 μ l were counted in Bray's solution in a Packard Model 3380 Tricarb Liquid Scintillation Spectrometer to determine the distribution of radioactivity. b, Sucrose density gradient centrifugation of nuclear RNA from PHA-stimulated normal lymphocytes. Lymphocytes were derived from normal donors by separation on nylon fibre columns¹⁰. PHA stimulation was done according to the method of Cooper¹⁰. For details of RNA extraction and separation see (a).

The conditions were standardised in that each gram of packed leukaemic cells derived from heparinised blood of untreated leukaemia patients was incubated at 37° C with 50 mCi ^{32}P -orthophosphate using a 1:100 ratio (w/w) of cells and medium. Nuclei were isolated after 6 h using 5% citric acid to prevent RNase degradation as described by Dounce⁶. The purified nuclear pellet was subjected to controlled hydrolysis with 1.0 mg highly purified DNase (Boehringer) per g nuclei in 1.5 ml 0.5 M NaCl, 0.05 M MgCl_2 , 0.001 M Tris, pH 7.4, at 22° C for 3 min. Buffer (40 ml) containing 0.1 M NaCl, 0.01 M Na acetate, 0.001 M MgCl_2 , pH 5.1, was added to 1 g of packed nuclei and the suspension was made 0.34% in sodium dodecylsulphate. The mixture was shaken with hot phenol at 65° C for 5 min as described by Scherrer and Darnell⁷. After two re-extractions with hot phenol, undegraded, highly labelled nuclear RNA was precipitated with two volumes of ethanol as demonstrated by sucrose density gradient centrifugations (Fig. 1a and b). A marked label was found in the 45S region and, in all experiments, only the three peak fractions were collected.

In a different batch, 1 g of cells derived from the same patient was incubated for 9 h using identical conditions and cytoplasmic RNA was extracted from a ribosomal preparation as described previously⁸. To eliminate the possibility of degradation, rRNA preparations were only used when they met the basic requirements of purity and quality as outlined by Attardi and Amaldi⁹.

Lymphocytes stimulated with PHA were prepared as described by Cooper¹⁰. In all experiments with both leukaemia cells and PHA-stimulated lymphocytes, nuclear 45S RNA and 28S rRNA were characterised by the determination of specific activities, nucleotide composition analyses, and oligonucleotide frequency studies after complete digestion of the RNA fractions with pancreatic RNase. The techniques of column chromatography on DEAE-Sephadex A25 and high voltage paper electrophoresis have been described elsewhere^{11,12}. The details of comparative structural studies of high molecular weight nuclear and rRNA species from various human leukaemias and lymphomas will be reported elsewhere (S.S., K.P.B., J.K., C.G.S. and H. Busch, unpublished).

Figure 1 shows the distribution of radioactivity in nuclear RNA fractions when separated on 6%–45% sucrose density gradients (pH 5.1) and fractionated into 58–60 portions of 0.6 ml. Some differences were found between the proportion of label in 45S, 35S and 28S RNA with a higher percentage of label in 45S in the case of AML (Fig. 1a and b). High specific activities up to 1.5×10^9 c.p.m. per mg RNA were

determined for the 45S fraction both from PHA-stimulated normal lymphocytes and leukaemic blast cells (Table 1). No major differences were found in nucleotide composition analyses (all run in triplicate) between two of three cell lines of human leukaemia and the transformed normal lymphocytes (Table 2). Table 2 also indicates that the RNA found in the 45S fraction was mainly of the preribosomal type with a G+C/A+U ratio of 1.96–2.00. Table 1 summarises the specific activities of nuclear 45S RNA and ribosomal 28S RNA from three individual experiments each with acute myeloblastic leukaemia cells and PHA-stimulated normal lymphocytes.

The striking differences found in the ratios of the specific activities, as well as the demonstration of very small amounts of label in 28S rRNA of blast cells clearly indicate a failure of rRNA synthesis in the leukaemia cells. Although there were some consistent differences in the ^{32}P -nucleotide compositions with equal labelling of guanylic and cytidylic acid in the case of the blast cells (the values for a number of tissues reported by Attardi and Amaldi⁹ correspond to those found for PHA-stimulated lymphocytes in our studies) no significant structural differences were found between 28S rRNA of leukaemic and non-leukaemic cells when the frequencies were determined for the partial sequences A-Cp, A-Up, G-Cp, G-Up, A-A-Cp, (A, G)-Cp, A-A-Up, G-G-Cp, G-A-Up, A-G-Up and G-G-Up (S.S., K.P.B., J.K., C.G.S., and H. Busch, unpublished).

These results, based on high specific labelling of nuclear and cytoplasmic RNA species, support the previous findings of a block in processing of the ribosomal precursor to the RNA of the mature ribosome in blast cells of human acute leukaemia. This condition, however, may not be unique to leukaemic blast cells since it has also been pointed out that processing of the ribosomal precursor may be different in actively growing cells, resting cells and cells under transition from the resting state to active growth¹³. It may be of interest that with the use of the same techniques we found similar small amounts of label in cytoplasmic RNA in acute lymphoblastic leukaemia (ALL) and chronic lymphocytic leukaemia (CLL). Conversely, high specific activities of 28S rRNA were determined in two cases of leukaemic lymphosarcoma and in a Burkitt lymphoma cell line (unpublished).

The transformation of chronic lymphocytic leukaemia into lymphosarcoma which has been reported many times may be, on a cellular level, characterised by an increased processing of preribosomal RNA. With our preparations of RNA from a monosome-polysome pellet we never found disproportionate labelling of 18S and 28S RNA with rela-

tively small amounts of label present in the 18S rRNA. It has been postulated that the assembly of ribosomes in normal and also leukaemic lymphocytes would be controlled by such a 'wastage' of 18S rRNA^{14,15}. These studies were, however, based on RNA extractions from unfractionated lymphocytes and showed very low label in the 18S fraction of resting normal and leukaemic lymphocytes.

Presence of a large poly(rC) tract within the RNA of encephalomyocarditis virus

THE replication of the RNA-containing bacteriophages has been found to involve specific replicases, partly coded by the phage genome (reviewed in refs 1 and 2). The replication proceeds by way of a partially double-stranded intermediate form, and the replicases must presumably recognise the 3'-terminal regions of the RNA (+) and (-) strands as start points for copying^{1,2}. There is also evidence that the Q β replicase recognises a specific internal region of the Q β RNA molecule, which is involved in forming a replicative complex³. Replication of the smallest animal RNA viruses, the picornaviruses, also requires specific replicases, and has a mechanism⁴⁻⁷ which is not dissimilar to that of the RNA phages, as far as it has been elucidated. We have been studying nucleotide sequences of regions of a picornavirus RNA which might be specifically recognised by its replicase, or have specific roles in the replicative process, in the same way that such sequences have been characterised in the RNA phages¹⁻³.

Encephalomyocarditis (EMC) virus, which is typical of the cardiovirus group of picornaviruses, contains a continuous single-stranded RNA molecule of molecular weight around 2.7×10^6 , about 7600 nucleotides in length (refs 8 and 9 and D. Frisby, unpublished). We have found a region of 95-100 nucleotides in the interior of the molecule, con-

taining 85-90 C residues. Here we describe the isolation and characterisation of this poly(rC) region, and discuss its possible significance.

EMC virus was cultivated in Krebs ascites cells in the presence of ³²P-orthophosphate, and radioactive virus was purified from the cell lysate in the way described in the legend to Fig. 1. The RNA was extracted from the purified virus by phenol-chloroform treatment. Subsequent sucrose gradient centrifugation of the RNA revealed a single peak, shown in Fig. 1, with a sedimentation coefficient of about 37S, corresponding to the size previously reported for EMC RNA (refs 8 and 9 and D. Frisby, unpublished). Electrophoresis of this RNA peak through 4% polyacrylamide gels containing formamide yielded a single high molecular weight band, demonstrating the absence of any hidden breaks in the purified material. We therefore suggest that the products

FIG. 1 Sucrose gradient profile of ³²P-labelled EMC RNA. The RNA was prepared as follows. A 100 ml suspension of washed Krebs ascites cells in HB-NE medium (New Earle's medium, containing in g l⁻¹: NaCl, 6.28; KCl 0.37; MgSO₄ · 7 H₂O, 0.18; phenol red, 0.0009; glucose, 1.8; CaCl₂ · 6 H₂O, 0.18; NaHCO₃, 3.3; penicillin G, 0.06; and streptomycin, 0.06; buffered to pH 7.5 with HEPES) containing 1.5×10^7 cells ml⁻¹ was infected with EMC virus at a multiplicity of 10 PFU per cell. To enable viral multiplication, the infected cell suspension was allowed to stand at 22° C for 0.5 h, then gently shaken in a 1 l flask for 3 h at 37° C. ³²P-orthophosphate was then added to a concentration of 0.1 mCi ml⁻¹, and shaken for a further 16-18 h during viral multiplication. The resulting lysate was centrifuged at 16,000g for 0.5 h at 4° C (MSE centrifuge) to remove cell debris. Labelled virus was pelleted from the supernatant by centrifugation (110,000g) for 2 h at 4° C (in the Beckman L2-50 ultracentrifuge) and the pellet partially resuspended in 1 to 2 ml of PBS-A buffer (containing in g l⁻¹: NaCl, 8.0; KCl, 0.2; Na₂HPO₄ · 1.15 g; KH₂PO₄, 0.2, pH 7.3), then left overnight at 4° C. Several volumes of PP8 buffer (0.1 M NaCl, 0.1 M K₂HPO₄ and 0.2 M Na₂P₂O₇ · 10 H₂O, pH 8.0) were added to this suspension to solubilise the virus, and the total volume was made up to 25 ml with additional PBS-A. The suspension was then layered onto a 10 ml sucrose cushion (29% sucrose in PBS-A) and centrifuged at 110,000g as above, but for 3 h. The second virus pellet was resuspended in PBS-A together with an equal volume of PP8, as described above, and layered onto an 11 ml 10.2-22.4 % isokinetic sucrose gradient in PBS-A buffer, and centrifuged for 75 min at 36,000 r.p.m. at 4° C in the SW41 rotor. Over 95% of the radioactivity on the gradient was always found in the 160S virus peak, which was extracted with equal volumes of Tris buffer-saturated phenol (pH 7.5) and chloroform, in the presence of 0.5% sodium dodecyl sulphate. The ³²P-labelled EMC RNA was precipitated from the aqueous phase by the addition of 0.5 mg of unlabelled carrier RNA, 0.1 volume of 2 M sodium acetate and 3 volumes of ethanol. This RNA was sedimented through a further similar sucrose gradient for 3.5 h, the profile of which is shown above. About 50 μg of labelled RNA with a specific activity of $0.5-0.8 \times 10^6$ c.p.m. μg⁻¹ was usually obtained.

TABLE 1 Analysis of the large T_1 RNase resistant oligonucleotides from EMC RNA. The products arising upon complete pancreatic RNase digestion of fragments A_0 - A_3 and α (Fig. 3) were excised, and the radioactivities of the spots on paper were determined directly by scintillation counting, enabling the quantities of the products, relative to Gp, to be estimated (column 3). All the estimates are calculated from the mean values of three determinations, and enable the lengths of the oligonucleotides to be approximately estimated, given in column 4. These lengths are consistent with the mobilities of the fragments relative to each other, and to the electrophoretic front in 10% polyacrylamide, and suggest that the fragments are homogeneous. This is also supported by the amounts of the fragments released upon hydrolysis of the RNA, about one mole of each per mole of RNA (Column 5). Their yields were determined by counting a small aliquot of an RNA digest (0.8%) before gel electrophoresis, and then counting the fractionated fragments following their elution from polyacrylamide onto DEAE-paper discs (this part of the elution procedure is quantitative since in multiple experiments the amount of residual ^{32}P counts remaining in the gel slice compared with that eluted onto the DEAE-paper discs was always less than 0.5%. No leakage of ^{32}P into the anode buffer compartment was detectable). Taking the length of the RNA as 7600 nucleotides (refs 8 and 9 and D. Frisby, unpublished), the total radioactivity of the RNA digest applied to the gel may be calculated in terms of c.p.m. per nucleotide, and thus also the expected radioactivities of fragments of these sizes, if each is present once. The observed molarities may then be calculated from comparison of the observed radioactivities with the expected radioactivities (Columns 5 and 6). In a typical experiment, 8.6×10^6 c.p.m. of digested EMC RNA were applied to a gel slab. The radioactivities of the fragments eluted were determined to be 92,000 c.p.m. (A_0), 36,700 c.p.m. (A_1), 46,300 c.p.m. (A_2) and 39,400 c.p.m. (A_3).

arising from subsequent nuclease digestion of this RNA cannot be derived from any contaminating low molecular weight material within the virus particles, whether or not associated with the EMC RNA. ^{32}P -labelled EMC RNA was completely digested with T_1 RNase, and the resulting products were fractionated through a large slab of 10% polyacrylamide gel containing 7 M urea, as described in the legend to Fig. 2. The products were located by autoradiography (Fig. 2).

The majority of the oligonucleotides migrate close behind the electrophoretic front, and are in the size range 1-25 nucleotides, as expected. Three larger products, A_1 , A_2 and A_3 are also found, of approximately 25-40 nucleotides. This also corresponds to the expected abundance of oligonucleotides of this size arising upon T_1 RNase digestion of an RNA of the size and composition of EMC. A further product, A_0 , however, containing 95-100 nucleotides by

analysis, is also present. This is much larger than any oligonucleotide which would be expected to arise from an RNA of 7,600 nucleotides in a random sequence, since the probability of a section of this length lacking any G residues is vanishingly small. Finally a further band, α , apparently slightly larger than A_0 , is found in small and variable amounts among the digestion products.

We have analysed the fragments A_0 - A_3 and α by further digestion with pancreatic RNase. The results of these analyses are reported in Table 1, and the fractionation of the products is shown in Fig. 3. The gel fractionation indicates that fragment A_2 must be a few nucleotides larger than A_3 , but our analyses are not sufficiently precise to show the exact size difference. Fragments A_1 , A_2 and A_3 display no unusual structural features, as judged from the results of these partial analyses. In particular, there is no preponderance of any one nucleotide in them.

Fig. 2 Fractionation of the products arising upon complete hydrolysis of EMC RNA with T_1 RNase. $2-40 \times 10^6$ c.p.m. of ^{32}P -labelled EMC RNA (5–50 μg , containing 500 μg unlabelled carrier tRNA) was dissolved in 0.02 ml of 0.02 M Tris HCl pH 7.4; 0.002 M EDTA (low salt buffer) containing T_1 RNase (Sankyo Ltd., Japan) at an enzyme: substrate (w/w) ratio of 1:40. Digestion was continued for a further 1 h at 37°C . Alternatively digestion was carried out in 0.02 M Tris HCl-0.02 M MgCl_2 (high salt buffer) at pH 7.5. No difference in the digestion pattern was observed. The RNA digest was mixed with an equal volume of 7 M urea containing 60% sucrose and a trace of bromophenol blue, and layered into a $0.1 \times 1 \times 5$ cm pocket at the top of a 10% polyacrylamide gel slab (measuring $0.3 \times 15 \times 40$ cm) made up in the following buffer: 0.1 M Tris borate, pH 8.3; 0.0025 M EDTA and 7 M urea. Electrophoresis was carried out in the cold for 16–18 h at 500 V and 30 mA. The radioactive bands were located by autoradiography, as shown above, and excised using the autoradiograph as a guide. Fragments A_0 – A_3 and α were eluted electrophoretically onto DEAE-cellulose paper discs which were washed in ethanol and counted to estimate the molar yields of the fragments (see legend to Table 1). Elution of the labelled fragments from the discs was performed using freshly-prepared 30% triethylammonium carbonate, pH 10, as described by Adams *et al.*²⁵

In contrast, the very large product A_0 contains 85–90 C residues, together with 3 As, 4 Us and the expected 3' terminal Gp. The estimated size of 95–100 nucleotides derived from this analysis is consistent with its position on the 7 M urea gel relative to the other fragments A_1 – A_3 . Estimates of the sizes of these are also included in Table 1. We have also determined the yields of the fragments α and A_0 – A_3 in terms of the numbers of moles of each which arise from each mole of EMC RNA upon enzymatic hydrolysis. These values are reported in Table 1. It may be seen that all of the fragments except α are equimolar, and each seems to occur once in the molecule.

The analysis of band α is also listed in Table 1. From its position on gel electrophoresis, the material contained in it is a few nucleotides longer than the fragment A_0 . On the basis of a length of 100 nucleotides it is present in roughly 0.3 M amounts in digests of the RNA. It has a complex composition. Like A_0 , it is very rich in C, but this may arise by contamination with A_0 because of 'tailing' of the latter fragment. It also contains more than one product terminating in Gp, in addition to Gp itself, which suggests that it might be a mixture of two or more components, each present in very small amounts in the digest. These might arise because of incomplete hydrolysis of a small proportion of the RNA, and this view is supported by the variable amounts of α present in digests. Perhaps this is due to incomplete deproteinisation of the RNA affording specific nuclease-resistant areas. This is purely speculative, however.

So far we have no direct evidence about the location of the poly(rC) tract within the EMC RNA; however an indirect argument suggests that it might be situated close to one of the termini. The aggregate molecular weight of the EMC virus-specified proteins has been estimated to be about 2.3×10^5 (ref. 10). The molecular weight of the RNA necessary to code for these proteins would be about 2.3×10^6 . Since the molecular weight of the EMC RNA is around 2.7×10^6 , there are roughly 1,000 nucleotides of untranslated RNA within the EMC viral genome. These

untranslated regions must be situated at the termini of the RNA, since the initial translation product is a single polypeptide¹⁰; that is, there are no untranslated areas between the cistrons. The poly(rC) tract would code for a polyproline region if it were translated. The amount of proline present in the proteins of the EMC viral capsid is relatively small¹¹; however, we cannot exclude the possibility that a polyproline tract is present in some other virally-specified protein within the host cell cytoplasm, although this seems unlikely. This suggests that the poly(rC) region is probably untranslated, and so occurs fairly close to one or other of the termini of the RNA molecule. If so, it would account for roughly 10% of the untranslated nucleotides.

Poly(rC)-enriched regions do not exist in bacterial tRNAs¹² or rRNAs^{13,14}, nor have they been detected within small phages such as Q β or R17 (refs 1 and 2 and A. G. Porter, unpublished). In the case of Q β RNA (A. G. Porter, unpublished), oligonucleotides resulting from complete T_1 RNase digestion were fractionated by electrophoresis followed by homochromatography^{15,16}. None of the largest T_1 RNase fragments (15–25 nucleotides) were found to be unusually rich in any one nucleotide. Preliminary analyses of the longest oligonucleotides arising from T_1 RNase digestion of influenza viral RNA and tobacco mosaic viral RNA^{17,18} have also not revealed poly(rC). Since poly(rC) areas have not been detected in any other naturally occurring RNAs, can any specific function be attributed to this region within the EMC RNA? Two observations suggest that the poly(rC) might be part of a site recognised by the EMC viral replicase at some stage in the replicative process. First, it has recently been reported¹⁹ that a partially purified EMC viral replicase preparation will synthesise poly(rG) from a poly(rC) template. Second, the Q β replicase, which has subunits of very similar size to those of the EMC replicase¹⁹, can also synthesise poly(rG) using a poly(rC) template, but cannot use other homopolymers or natural nucleic acids as templates, except the Q β RNA itself^{20,21}. As mentioned above, however, the Q β RNA does not contain a T_1 RNase-resistant tract of poly(rC) comparable in length with that of EMC RNA (refs 1 and 2 and A. G. Porter, unpublished), and therefore the significance of this observation remains unclear. The suggestion that the poly(rC) region in EMC RNA might function in replication is reinforced if, as seems likely, the poly(rC) tract lies close to one of the termini in a non-coding area of the RNA.

About 60% of the nucleotides in the EMC RNA participate in secondary structure when the RNA is in free solution (D. Frisby and R. Cotter, unpublished). If the poly(rC) tract is involved in this secondary structure, a corresponding area rich in poly(rG) would be expected in the EMC RNA. Complete digestion of the RNA with pancreatic RNase, however, does not give products longer than 15–20 nucleotides (our unpublished results), excluding the presence of long uninterrupted tracts of poly(rG). Therefore any secondary structure involving the poly(rC) region would contain substantial mismatching, although no conclusions can yet be drawn regarding the presence or absence of such secondary structure.

No products containing extended tracts of poly(A) occur among the large oligonucleotides arising from T_1 RNase digestion of EMC RNA in either high salt or low salt conditions. These ought to be detectable in the same way as other large oligonucleotides, if present, and it therefore seems that the RNA, at least within the virus particle, lacks any appreciable poly(A). Similar findings have been reported for the closely related cardiovirus Mengo²², where the maximum length of the poly(A) tracts has been estimated to be about 16 nucleotides. We have not yet systematically examined the smaller EMC RNA oligonucleotides in this size range, and therefore we do not know whether any

FIG. 3 Fractionation of the products of pancreatic RNase digestion of the large fragments from EMC RNA. The fragments A_0 - A_3 and α (Table 1) were completely digested with pancreatic RNase as described by Brownlee *et al.*^{15,16} and the products fractionated by electrophoresis on DEAE paper at pH 3.5 (0.5% pyridine-5% acetic acid). The positions of the radioactive spots were determined by autoradiography, as shown above, and the oligonucleotides quantified by counting and eluted^{15,16}. In most cases, the pancreatic oligonucleotides could be identified from their positions on the autoradiograph. In all cases, however, firm identification was made (Table 1) by total alkaline hydrolysis of every oligonucleotide, followed by fractionation of the products by electrophoresis on Whatman No. 52 paper at pH 3.5 (refs. 15 and 16). In one experiment, oligonucleotides arising from pancreatic RNase digestion of fragments A_0 - A_3 were separated by two-dimensional electrophoresis (on cellulose acetate at pH 3.5 and DEAE paper in 7% formic acid^{15,16}). The pancreatic RNase digest of fragment A_0 was fractionated in two tracts in order to obtain a mean count of each oligonucleotide present.

short poly(A) stretches are present in the EMC RNA. The cardioviruses therefore seem to differ in this respect from polio, an enterovirus, which has been reported to contain about 50 (ref. 23) or 90 (ref. 24) A residues at its 3'-terminus.

We are now examining the RNAs of a number of other picornaviruses for the presence of poly(rC) tracts, and attempting to determine the location of the poly(rC) region in the EMC RNA directly by sequencing.

We thank C. Newton for technical assistance, D. Frisby, I. Lindley, Dr N. Stebbing and Dr A. E. Smith for their valuable discussions and help. We also thank Drs H. Gould

and M. Szekely for very kindly providing electrophoresis equipment while we awaited delivery of our own.

In vivo and in vitro effect of α -amanitin on preimplantation mouse embryo RNA polymerase

THE effects of various metabolic inhibitors, including actinomycin D, puromycin, cycloheximide, mitomycin C, and fluorophenylalanine, on preimplantation mouse embryos have been previously studied¹⁻⁶, to investigate when RNA synthesis begins in preimplantation embryos and what types of RNA are synthesised during the various stages of development. Monesi and Salfi³ originally reported that there was no appreciable overall RNA synthesis until the morula stage. Ellem and Gwatkin⁷ also found no detectable RNA synthesis at the two-cell stage of development. Recently, using more

sensitive techniques, RNA synthesis has been detected as early as the two-cell stage of development⁸⁻¹⁰. We assumed that since RNA synthesis occurs in preimplantation mouse embryos, the enzyme, DNA-dependent RNA polymerase, must be active. We report here the results of *in vivo* and *in vitro* experiments intended to characterise more fully the RNA polymerase present in preimplantation mouse embryos. We used the mushroom toxin, α -amanitin, to determine which forms of RNA polymerase are active and the relative amounts of each form which are present in preimplantation mouse embryos.

In an earlier study¹¹ we reported the existence of three forms of DNA-dependent RNA polymerase in the nuclei of adult mouse liver. It was determined that two of the forms, IA and IB, were resistant to an α -amanitin concentration of $0.3 \mu\text{g ml}^{-1}$ whereas form II was completely inhibited by this amount of toxin. These findings are in general agreement with those of Roeder and Rutter¹² in which it was further determined that form I polymerase is found primarily in the nucleolus and synthesises ribosomal-like RNA while form II is found in the nucleoplasm and synthesises a DNA-like RNA. We thought it should be possible, then, to ascertain whether RNA polymerase form II is active in synthesising mRNA in preimplantation mouse embryos.

A first set of experiments was designed to test the *in vivo* effects of α -amanitin. Preimplantation mouse embryos at the two-cell stage of development were collected from CF1 female mice (Carworth Labs, Inc., Portage, Michigan) after superovulation with 5 IU pregnant mare serum (PMS), (Organon) followed 48 h later by 5 IU human chorionic gonadotropin (HCG), (Nutritional Biochemical). The embryos were collected and washed in Whitten and Biggers medium¹³ and cultured in microdrops of medium (containing one or two embryos) under oil which had been preequilibrated with the medium. The cultures were maintained at 37°C in an atmosphere of 5% CO_2 , 5% O_2 , 90% N_2 . When α -amanitin was used as an inhibitor, it was added to the medium in which the embryos were collected, and was present throughout all further manipulation including equilibration of the oil. The embryos were scanned visually for stage of development 48 h after being introduced into microdrop culture. The results of these experiments are shown in Table 1. It is seen that 17% of the normal embryos failed to develop past the two-cell stage under our culture conditions. The effect of α -amanitin was to arrest development at the two-cell stage with $1 \mu\text{g ml}^{-1}$ of α -amanitin arresting 71% of the embryos

tested. It is interesting to note that although 67% of the untreated embryos developed to the morula or blastocyst stages less than 1% of the embryos which had been treated with $1 \mu\text{g ml}^{-1}$ of α -amanitin developed to the morula or blastocyst stages.

From the *in vivo* experiments reported above it seems that RNA polymerase is indeed active as early as the two-cell stage of development in the mouse. Exactly which of the multiple RNA polymerases is inhibited remains an open question. Although it is generally agreed that *in vitro* only the nucleoplasmic form of the enzyme is inhibited, Tata *et al.*¹⁴ have shown that *in vivo* both the nucleoplasmic and nucleolar polymerases may be inhibited.

For *in vitro* experiments with solubilised enzyme, CF1 mice were superovulated as described earlier and blastocysts collected 86-92 h after HCG injection. The embryos were treated with Pronase to remove the zona pellucida, washed three times in Whitten and Biggers medium, washed once in 0.01 M Tris pH 7.4, 0.5% BSA, and taken up in $10 \mu\text{l}$ of the same buffer. The embryos were frozen and thawed three times in liquid nitrogen. $2.5 \mu\text{l}$ of $2.75 \text{ M } (\text{NH}_4)_2\text{SO}_4$ (pH 7.9) were then added to bring the $(\text{NH}_4)_2\text{SO}_4$ concentration to 0.55 M. $25 \mu\text{l}$ of TGMED (0.05 M Tris-HCl, pH 7.9; 25% glycerol; 5 mM MgCl_2 ; 0.1 mM EDTA; 0.5 mM dithiothreitol) or TGMED containing the desired concentration of α -amanitin were then added followed by $37.5 \mu\text{l}$ of assay mixture. The final reaction mixture ($75 \mu\text{l}$) contained: 36 μg calf thymus DNA, 50 mM Tris-HCl, pH 7.9, 2 mM MnCl_2 , 1.6 mM MgCl_2 , 6 mM NaF, 8 mM KCl, 0.5 mg ml^{-1} BSA, 0.3 mM spermine, 0.5 mM dithiothreitol, 0.6 mM ATP, 0.6 mM GTP, 0.6 mM CTP, 0.004 mM ^3H -UTP (New England Nuclear, specific activity 26.9 Ci mmol^{-1}), 3 μg pyruvate kinase (Sigma, 320 units mg^{-1}), 4 mM phosphoenolpyruvate, 0.09 M $(\text{NH}_4)_2\text{SO}_4$, 8.3% glycerol, 0.03 mM EDTA. The reaction mixture was incubated at 37°C for 40 min and the amount of incorporated ^3H -UMP determined by the method of Litman¹⁵.

The RNA polymerase activity of blastocysts in the presence and absence of $1.1 \mu\text{g ml}^{-1}$ α -amanitin is shown in Table 2. We show data from two experiments, B12 and B13. The average values reported as ^3H -UMP incorporated per embryo per min ($\text{pmol} \times 10^{-5}$) are 2.70 ± 0.42 without α -amanitin and 1.83 ± 0.29 with α -amanitin. This corresponds to 32% inhibition of enzyme activity by $1.1 \mu\text{g ml}^{-1}$ α -amanitin. The average values for experiment B12 alone are 3.09 without α -amanitin and 2.01 with α -amanitin, whereas the average values for experiment B13 alone are 2.44 without α -amanitin and 1.57 with α -amanitin. This corresponds to 35% inhibition in experiment B12 and 36% inhibition in experiment B13. We have found that these types of experiments are always internally consistent, but absolute values may vary from one experiment to another, as illustrated by the data for experiments B12 and B13. For this reason our experiments always include several samples without α -amanitin as a control.

Figure 1 shows the inhibition of mouse blastocyst RNA polymerases by varying doses of α -amanitin. The assays were all performed at high ionic strength, which favours the detection of form II RNA polymerase. When these experiments were repeated at low ionic strength, the results shown in Table 3 were obtained. It is seen that the blastocyst enzymes are inhibited 6% at low ionic strength compared

FIG. 1 Inhibition of RNA polymerase activity against concentration of α -amanitin for mouse blastocyst enzymes.

with a maximum of 35% at high ionic strength. In contrast, the adult fraction 4 (F4) enzymes showed 50% maximal inhibition at low ionic strength and 82% maximal inhibition at high ionic strength. We also found that a concentration of 0.30 mg ml^{-1} causes maximal inhibition of F4 and form II adult enzymes, while a concentration of $0.8 \text{ } \mu\text{g ml}^{-1}$ of α -amanitin was necessary for maximal inhibition of the embryonic enzymes (compare Fig. 1 with Table 3). Therefore, it seems that the blastocyst enzymes are less sensitive to inhibition by α -amanitin than are the adult liver enzymes.

There are several possible explanations for these observations. First, it is possible that differences in the solubilisation process for the liver and embryonic polymerases may alter their properties. A second possibility which may effect the α -amanitin sensitivity of the enzymes is the amount of endogenous template present before the addition of α -amanitin. In the embryo experiments no attempt was made to remove the endogenous template while there is very little or no endogenous template present in the solubilised liver enzyme preparation (unpublished observation).

The most attractive possibility is that the difference in maximal inhibition of total RNA polymerase solubilised from blastocysts (35%) and liver nuclei (82%) may indicate that the relative proportions of form I and form II polymerases are different in adult and embryonic tissues and that more form I is present (relative to form II) in blastocysts than in adult liver nuclei. This, as well as the *in vivo* results, represents presumptive evidence for the direct involvement of the various forms of RNA polymerase in the regulation of RNA synthesis in preimplantation mouse embryos.

The question of whether the number of RNA polymerase molecules per cell correlates with the amount of RNA syn-

thesised at any given stage in embryonic development is controversial. Siracusa¹⁶ has reported in a preliminary note that there is no such correlation in mouse embryos from the fertilised egg to the blastocyst stage. Roeder *et al.*¹⁷ also found no such correlation in *Xenopus laevis*, but did find a correlation between the rate of RNA synthesis and the levels of RNA polymerase per cell in the sea urchin¹⁸.

The control of RNA synthesis, however, may be more dependent on the types of RNA polymerase present in early embryos, than on the total amount of enzyme present. The former could specifically control which RNA species were synthesised at any given time, whereas the latter would at best be a reflection of total RNA synthesis. We have shown that at least two distinct forms of RNA polymerase activity, based on their inhibition by α -amanitin, are present in preimplantation mouse embryos. We are currently trying to show which types of RNA are synthesised by the different forms of the enzyme at various stages in preimplantation mouse development.

We thank Professor T. Wieland for the α -amanitin. This work was supported by a grant from the Population Council, New York.

* F4, is the mixture of RNA polymerases from adult mouse liver directly before DEAE-Sephadex chromatography; Forms IA, IB and II are the isolated enzyme forms after DEAE-Sephadex chromatography (see Versteegh and Warner¹¹). Blastocyst enzyme is as described in the text.

Bacteriophage of *Halobacterium salinarum*

Halobacterium salinarum is a member of the Halobacteria, a group of obligate, extremely halophilic organisms requiring at least 15% NaCl in their growth media. No bacteriophage has previously been found in association with members of this group.

H. salinarum strain 1 was cultivated as described by Dundas *et al.*¹. During an investigation of flagella from *H. salinarum*, phage particles were observed in some crudely purified flagellar preparations. Phage-containing preparations did not give rise to plaques when plated with exponentially growing *H. salinarum* cells. Attempts at ultraviolet induction of *H. salinarum* cultures resulted in normal death curves

without any concomitant phage production. Maintenance of batch cultures, started from isolated *H. salinarium* colonies, in the logarithmic phase of growth, by means of serial transfer of cultures in late log phase to fresh media, resulted in eventual lysis of the cultures. Lysis may occur after the first transfer or be delayed for more than six transfers.

FIG. 1 Electron micrographs of preparations from *H. salinarium* culture lysates. All preparations were negatively stained with uracyl acetate. The scale bar is 0.1 μ m.

In these experiments the cultures initially exhibited normal generation times of 6.1 to 6.7 h. Before lysis, culture generation time increased to more than 10 h. At this point cultures would lyse in 24–48 h after entering late logarithmic growth phase. Lysis took place both in cultures stored without aeration at room temperature and in cultures incubated with aeration at 37°C. Normal cultures (generation time 6–7 h) will not lyse when incubated for more than a week with or without aeration, at 37°C or at room temperature.

All culture lysates produced in this manner contained phage particles. (Fig. 1). Phage particles have not yet been found by routine electron microscopic examination of normal cultures at any stage of growth. The phage particles have an isometric polyhedral head and a contractile tail. The dimensions of the particles are quite uniform.

The existence of bacteriophage for *Halobacterium* opens the existing possibility of further exploration of the genetic basis of extreme halophilism.

Further observations on the structure of the lipid-containing bacteriophage PM2

RECENT work on the proteins of bacteriophage PM2 have led us to a model for the structure of this virus, proposed in this communication. Experimental results have enabled us to assign each of the four proteins¹ to morphological structures of the virus revealed by electron microscopic and structural studies. Packing considerations indicate that protein II must form the outer protein shell². Both proteins I and II are on the outside of the phage particle as demonstrated by labelling with radioactive iodine after lactoperoxidase treatment³ by the method of Phillips and Morrison^{4,5}.

In agreement with these results we have now shown that protein I can be selectively removed by digestion with bromelain, a proteolytic enzyme. Furthermore protein II can be labelled with ³⁵S-sulphanilic acid-diazonium salt by the method of Berg⁶ (Fig. 1). We have also isolated a nucleocapsid core by dissociation of the virion in 4.5 M urea. This core, which has an approximate $S_{20,w} = 133$ and which has been identified by electron microscopy as a well-organised icosahedrally-shaped core structure, contains all protein III and IV, as well as the viral DNA, but no phospholipids and

FIG. 1 a, Digestion of protein I by bromelain ³H-amino acid-labelled PM2 virus was added to 1 ml of 0.01 M sodium phosphate buffer (pH 7.0), containing 0.1 M NaCl, 0.001 M CaCl₂. After the addition of 1 mg bromelain, the mixture was incubated at 30°C for 3 h. The ratio of PM2 protein to protease was 0.1. At the end of the incubation, the mixture was chilled on ice. The protease was separated from PM2 on a sucrose step gradient, containing 20%, 40%, and 60% sucrose layers. Centrifugation was carried out at 120,000g for 1 h. After centrifugation, the virus band was collected and subjected to SDS-gel electrophoresis¹. In a control experiment (b) the virus was prepared for gel electrophoresis by the same procedures as described above, without digestion with the proteolytic enzyme. In both cases, after gel electrophoresis the gels were frozen and sliced into 0.9 mm fractions. The slices were placed in glass vials containing 8 ml toluene-PPO-POPOP-mixture and 3% Protosol. Vials were incubated with shaking overnight at 37°C and counted in a Packard liquid scintillation counter.

Fig. 2 Estimation of the isoelectric points of the individual PM2 proteins by cellulose-acetate electrophoresis. Before electrophoresis, cellulose-acetate sheets (4×17 cm) were equilibrated for 10 min in separation buffers (0.5 M Tris acetate pH 5, 7, or 9; 6 M urea, 0.02 M 2-mercaptoethanol). Protein solutions (5–20 μ l) (10–20 mg ml⁻¹ PM2 virus) were applied to the gel with a polyethylene capillary tip. Electrophoresis at the different pH values were carried out in a moist chamber on a refrigerated Teflon-coated surface for 90 min at constant voltage (40 V cm⁻¹). After electrophoresis, the protein was stained with a 0.25% (w/v) amido black 10B solution which contained methanol, water, acetic acid (45:45:10 (v/v)). The solvent (without amido black) was used for destaining. The running distances of the individual PM2 polypeptides and reference proteins (not shown) were plotted against the different pH values. To determine the isoelectric points these mobilities were extrapolated to zero mobility.

no protein I and II. Thus protein II, the major viral protein, forms the outer icosahedral shell; proteins III, IV and the DNA the inner icosahedral shell of the nucleocapsid, and the phospholipid bilayer is sandwiched between these two shells. Protein III probably forms the protein bridges⁷ which connect the inner and outer shells through the bilayer. From preliminary electron microscopic studies and from experiments showing that the phage cannot bind to its host cell after digestion of protein I, we imagine that protein I must form the outer spikes found at the vertices of the icosahedron.

We also measured the isoelectric points of the four viral proteins. These were determined on disrupted virus particles by electrophoresis on cellulose acetate strips at various pH values. The mobilities were extrapolated to zero mobility, a method preferable to isoelectric focusing in which the virus proteins precipitate near the isoelectric point. Whereas proteins I, III, and IV have isoelectric points at slightly less than neutrality (pH 6.2, 5.8, and 5.5, respectively), the isoelectric point of protein II is 12.3 (Fig. 2). Thus whereas proteins I, III, and IV are slightly negatively charged at pH 7.0, protein II is strongly positively charged.

From previous studies, PM2 contains 12.6–14.0% of phospholipid, of which 64% is phosphatidylglycerol (PG) and 27% is phosphatidylethanolamine (PE)^{8,9}. These ratios of phospholipids are essentially the inverse of those of the host cell (23% PG and 75% PE)⁸. As PG is negatively charged and PE is neutral at neutral pH values, we propose that electrostatic interactions between protein II and PG must play a major role in the structural integrity as well as in the assembly of phage PM2. We predict that there must be a very strong asymmetry in the bilayer, with PG preferentially located in the outer lamella of the bilayer. From calculations of the number of PG molecules and the amount of positive charge due to protein II there is more than enough positive charge to neutralise the charge on PG, as well as

the excess negative charge of proteins I, III, and IV. Experiments to test the hypothesis of bilayer asymmetry, as well as experiments to determine the electrophoretic mobility of the virion are now in progress. Bilayer asymmetry has already been demonstrated for the erythrocyte membrane^{10,11}.

From a study of the origin of the viral phospholipids it is clear that the difference in viral phospholipid composition from that of the host cell must be due to selective processes occurring during virus assembly¹². There are active selective processes (biochemical processes) involving phospholipid synthesis and hydrolysis¹². There must also be passive (physical) selective processes and we propose that the electrostatic interaction of protein II with PG must play a major part in this latter process. Our present studies on PM2 structure, synthesis, and assembly should provide valuable information on protein-protein and protein-lipid interactions in the formation of one type of natural bilayer.

Fucosylglycolipids in cells transformed by a temperature-sensitive mutant of murine sarcoma virus

We have reported that fucosylglycolipid metabolism is markedly altered in cells transformed by oncornavirus¹. Transformed cells exhibit a sharp decrease in radioactive fucose incorporation into a chromatographically less mobile fucosylglycolipid, with a corresponding increase in radioactivity in chromatographically more mobile fucosylglycolipids. We describe here further studies of fucosylglycolipid metabolism using normal rat kidney (NRK) cells transformed by a cold-sensitive mutant of murine sarcoma virus (MSV)². The cell line, designated NRK (MSV-1b), is cold sensitive for maintenance of the transformed phenotype. The cells express the transformed phenotype at the permissive temperature (39° C) but appear phenotypically normal at the non-permissive temperature (33° C). Cells transformed by this mutant are non-producer cells, but contain the MSV genome in a rescuable form. Using these cold-sensitive transformants, we were able to demonstrate, in a temporal fashion, a relationship between altered fucosylglycolipid metabolism and the development of the transformed phenotype.

TABLE 1 Incorporation of ^{14}C -fucose into glycolipids of normal (NRK), NRK (MSV-1b) at non-permissive and permissive temperatures, and transformed NRK (MSV-MLV) cell lines

Fucosylglyco- sphingolipid	1 NRK (normal)		2 NRK (MSV-1b) at 33°C (non-permissive)		3 NRK (MSV-1b) at 39°C (permissive)		4 NRK (MSV-MLV) (transformed)	
	Compound	% c.p.m. per mg protein	Compound	% c.p.m. per mg protein	Compound	% c.p.m. per mg protein	Compound	% c.p.m. per mg protein
FucCer I	1.6	121	1.3	100	1.5	91	3.8	316
FucCer II	2.3	174	4.0	308	4.6	280	5.6	466
FucCer III	24.0	1814	27.6	2127	65.8	3999	80.5	6700
FucCer IV	72.0	5443	67.0	5163	28.1	1702	10.1	832

Culture conditions and thin-layer chromatography are described in Fig. 1. Compounds were located by autoradiography on Kodak No-screen X-ray films, scraped and quantitated by scintillation spectroscopy. Protein determination was carried out by the Lowry method. Permissive temperature (that is, phenotypically transformed) was 39° C; non-permissive temperature (that is, phenotypically normal) was 33° C.

All cells were grown in glass bottles in Eagle's minimal essential medium (MEM) supplemented with 10% foetal calf serum (v/v). Cell monolayers were washed three times with phosphate-buffered saline (PBS), removed by scraping into PBS and sedimented to a pellet. The pellet was washed with PBS and the lipid was extracted¹. The fucosylglycolipids were characterised as previously described¹, with the additional observation that pronase treatment³ had no effect on the chromatographic behavior of the fucosylglycolipids.

To investigate fucosylglycolipid metabolism at permissive and non-permissive temperatures, cells were seeded in medium supplemented with 0.5 $\mu\text{Ci ml}^{-1}$ of U- ^{14}C -L-fucose (133 mCi mmol⁻¹, Amersham/Searle, Arlington Heights, Illinois) and were grown at either 33° C or 39° C until they reached confluence (~ 72 h). On a protein basis, comparable amounts of radioactivity were incorporated into the fucosylglycolipids of uninfected NRK cells, the NRK (MSV-1b) cells grown at the permissive or non-permissive temperature, and into NRK cells transformed by the Moloney leukaemia-sarcoma virus complex (NRK (MSV-MLV), Table 1). Approximately equal amounts of radioactivity were chroma-

tographed (Fig. 1), and the major radioactive areas were excised from the plate and counted (Table 1). Consistent with the previous study¹ of other oncornavirus-transformed cell lines, there was a considerable alteration in the pattern of fucose labelling of glycolipids of the virus-producing, transformed NRK (MSV-MLV) cells (Fig. 1, lane 4; Table 1, column 4) compared with uninfected NRK cells (Fig. 1, lane 1; Table 1, column 1). NRK (MSV-MLV) cells exhibited a marked decrease in the amount of the chromatographically less mobile fucosylglycolipid (FucCer IV) with a concomitant increase in the chromatographically more mobile FucCer III. The fucosylglycolipid patterns of uninfected NRK cells and of NRK (MSV-MLV) cells were the same in cells cultured at 33° C or 39° C. Examination of the fucosylglycolipid pattern of cold-sensitive NRK (MSV-1b) cells grown at permissive temperature (Fig. 1, lane 3; Table 1, column 3) revealed a pattern which resembled the transformed NRK (MSV-MLV) cells. However, the inhibition of synthesis of the chromatographically less mobile component (FucCer IV) was not as marked in the NRK (MSV-1b) cells grown at permissive temperature as in the NRK (MSV-MLV) cells. In this regard, other measurements at permissive temperature (for example, sugar transport and saturation density)⁴ suggest less expression of viral transforming function in cells transformed by the cold-sensitive mutant compared with cells transformed by the parental strain of MSV-MLV. Examination of the fucosylglycolipid pattern of NRK (MSV-1b) cells grown at the non-permissive temperature (Fig. 1, lane 2; Table 1, column 2) demonstrated a striking resemblance to the pattern observed with normal cells.

We next measured the effect of temperature shift of NRK (MSV-1b) cells on fucosylglycolipid synthesis. Based on the results of the above experiments, reciprocal temperature-shift studies were performed to examine, in a temporal fashion, the relationship between fucosylglycolipid metabolism and the appearance of the transformed phenotype. Twenty-four hours after shifting to the permissive temperature, there were no marked morphological changes, and the fucosylglycolipid profile was comparable with cultures maintained at nonpermissive temperature (Fig. 2a and b, 24 h). After 48 h most cells were morphologically transformed and the fucosylglycolipid pattern of these cultures resembled that of cultures maintained continuously at the permissive temperature rather than of those maintained continuously at the non-permissive temperature (Fig. 2, a compared with b and c, 48 h). There was an increase in FucCer III, and decreases in FucCer I, II and IV. After 72 h the cultures shifted to the permissive temperature were essentially all transformed and the fucosylglycolipid pattern was the same as that of cultures maintained continuously at the permissive temperature (Fig. 2b and c, 72 h). On the other hand, 24 h after the reciprocal shift from permissive to non-permissive temperature, both the morphology and fucosylglycolipid pattern (Fig. 2d, 24

Fig. 1 Autoradiogram of the ^{14}C -fucose-labelled glycolipids from: (1) NRK cells, (2) NRK (MSV-1b) cells grown at 33° C (non-permissive temperature), (3) NRK (MSV-1b) cells grown at 39° C (permissive temperature) and (4) NRK (MSV-MLV) transformed cells. Culture conditions and lipid extraction are described in the text. Lipids were chromatographed on hard silica gel plates 'Q5' (Quantum Industries, New Jersey) in 2-propanol-ammonia (specific gravity 0.88)-water (7:2:1, by volume). Tentative identification of GDP-fucose and fucose- PO_4 is based on chromatographic similarities to several sugar-nucleotides and sugar-phosphates in ethanol-1 M ammonium acetate (7:3, v/v; pH 7.5). The radioactivity of these components has been excluded from the calculations in Table 1.

Fig. 2 Profiles of ^3H -fucose-labelled glycolipids after reciprocal temperature shifts. NRK (MSV-1b) cells were grown at either 39°C (permissive (P) temperature) or 33°C (non-permissive (NP) temperature) for 72 h before addition of isotopically-labelled fucose to minimise possible cell density-dependent effects on glycolipid synthesis⁵. The medium was then removed and fresh medium containing $1\text{-}^3\text{H-L-fucose}$ ($5\text{ }\mu\text{Ci ml}^{-1}$, 1.4 Ci mmol^{-1} , Amersham/Searle) was added. Half the cultures grown at 33°C (NP) were shifted to 39°C (NP \rightarrow P), while half of those at 39°C (P) were shifted to 33°C (P \rightarrow NP). At successive 24 h intervals thereafter, the cultures were examined morphologically and the fucosylglycolipids were analysed. Chromatography was carried out as in Fig. 1. The thin-layer plates were scraped and the major fucosylglycolipids (see Fig. 1) were counted by scintillation spectrometry. a, NP; b, NP \rightarrow P; c, P; d, P \rightarrow NP.

h) were comparable with cultures maintained at the permissive temperature. After 48 h many of the cells appeared morphologically normal and the fucosylglycolipid pattern resembled that of cultures maintained at the non-permissive temperature (that is, decrease in FucCer III, increase in FucCer I, II and IV). After 72 h essentially all the cells shifted to the non-permissive temperature appeared morphologically normal and the fucosylglycolipid pattern was comparable with that of cultures maintained continuously at the non-permissive temperature (Fig. 2a, 72 h) rather than that of cells maintained at the permissive temperature (Fig. 2c, 72 h).

These data show that alterations in fucosylglycolipid metabolism are related directly to the expression of the transformed state, and are not simply the result of MSV infection. The fucosylglycolipid pattern of NRK (MSV-1b) cells grown continuously at permissive temperature closely resembles the fucosylglycolipid pattern of cells transformed by the wild-type parent strain of MSV-MLV. In a parallel fashion, the fucosylglycolipid pattern of NRK (MSV-1b) cells grown continuously at non-permissive temperature resembles that of normal cells. In contrast, studies of nonfucose glycolipids (that is, gangliosides and their neutral glycolipid precursors) involving hamster cells infected with a temperature-sensitive (ts) transformation mutant of polyoma virus⁵ or chick embryo cells with a ts transformation mutant of Rous sarcoma virus⁸ have revealed similar non-fucose glycolipid patterns at both permissive and non-permissive temperatures. In addition, kinetic studies using the cold-sensitive NRK (MSV-1b) cells in temperature-shift experiments revealed a relationship between the morphology of the transformed cell phenotype and altered fucosylglycolipid synthesis. The relative rapidity of the fucosylglycolipid alterations after temperature-shift as compared with the stable pattern of the non-fucose glycolipids^{3,5}, suggests a unique and dynamic role for fucosylglycolipids in transformation.

Carbohydrate groups in the major glycoprotein of Rous sarcoma virus

GLYCOPROTEINS and other complex carbohydrates on the cell surfaces have been thought to be involved in many biological interactions¹. Most enveloped viruses contain at least one glycoprotein component¹. In avian sarcoma and leukaemia viruses some of the glycoproteins are located on the surfaces of the particles as projections composed of spikes and knobs²⁻⁴. Although their role is not well understood, the glycoproteins are believed to be involved in the determination of host range specificity, induction of neutralising antibody and interference capacity^{2,5-11}. Rous sarcoma virus contains several glycoproteins¹⁰⁻¹³, and infectious and non-infectious strains of Rous sarcoma virus differ in major glycoprotein components^{14,15}. We report here the results of purification of the major glycoprotein component (g2) of Rous sarcoma virus, its amino acid composition, and the nature of its carbohydrate groups.

The Bryan high-titre strain of Rous sarcoma virus RSV (RAV-1) was grown in type C/O or C/B chick embryo

TABLE 1 Amino acid composition of glycoprotein g2

Amino acid	Mol %
Lys	3.66
His	2.81
Arg	4.47
Asp	11.26
Thr	7.56
Ser	8.47
Glu	11.70
Pro	6.97
Gly	9.33
Ala	5.24
Cys	—
Val	5.36
Met	1.34
Ileu	3.90
Leu	8.33
Tyr	4.51
Phe	5.07

The glycoprotein, with added norleucine standard, was hydrolysed in 6 N HCl for 22 h at 105°C . Amino acid analysis was performed on a Technicon TSM amino acid autoanalyser.

Fig. 1 Chromatography of viral proteins with Bio-Gel P-150. A, The phenol-extracted proteins of RSV(RAV-1) were passed through a column and fractions 35-40 (3.6 ml per fraction) were combined for rechromatography. B, The optical density profile after rechromatography of fractions 35-40 from (A). Fractions 36-43 were combined for further purification. C, Chromatography of the combined fraction from (B). Fractions 36-40 which contain homogeneous g2 glycoprotein by SDS-gel electrophoresis, were combined for the studies of amino acid and sugar compositions.

fibroblasts in an appropriate growth medium¹⁶. Large quantities of virus were isolated and purified from 40-60 l of culture medium by differential centrifugation and isopycnic banding as described before¹⁷. Viral protein was extracted with phenol from a preparation containing about 550 A_{280} units of purified RSV(RAV-1) in the presence of sodium dodecylsulphate (SDS) and EDTA as reported earlier¹⁸. The viral protein was dissolved at 56°C in 0.1 M Tris buffer, pH 8.3 containing 6 M urea and 1% mercaptoethanol. Gel-filtration chromatography was carried out on a column of Bio-Gel P-150 (2.7 × 93 cm) in sodium phosphate buffer, 0.01 M, pH 7.2, and 0.1% mercaptoethanol. To locate glycoprotein g2, aliquots from the collected fractions were electrophoresed in SDS gels¹³ and stained with Coomassie brilliant blue. The glycoprotein was detected in the trailing region, fractions 35-40 (Fig. 1A) of a peak near the void volume. Rechromatography of the trailing region on the same column showed two peaks (Fig. 1B). Rechromatography of fractions 36-43 (Fig. 1B) produced a peak containing only the glycoprotein g2 as analysed in SDS gel electrophoresis (Fig. 2). In a typical run, about 1.8 A_{280} units of the protein were isolated.

Amino acid and sugar compositions (Tables 1 and 2) indicate that g2 is composed of 40% by weight of carbohydrate. A preparation containing 1.8 A_{280} units contained 0.95 mg of peptide and 0.68 mg of carbohydrate. The minimal molecular weight calculated from the results of Tables 1 and 2 is about 12,500. From SDS-gel electrophoresis results, the

TABLE 2 Sugar composition of glycoprotein g2

Sugar	$\mu\text{mol per mg peptide}$
Glucosamine	1.36
Mannose	1.20
Galactose	0.64
Fucose	0.10
Sialic acid	0.40

Hydrolysis conditions were as follows: for glucosamine, 4 N HCl for 6 h at 100°C; for neutral sugars, 2 N trifluoroacetic acid for 2 h at 100°C; for sialic acid, 0.05 N H_2SO_4 for 1 h at 80°C. Amino sugars and neutral sugars were determined by automated assay as described^{19,20}. Electronic expansion of the signal from the colorimeter by means of a linear converter (Dynacon Research and Systems, Pallisades, New York) facilitated determination of 0.001 to 0.02 μmol of amino sugars. Sialic acid was assayed with autoanalytical chromatography (our work to be published) using the thiobarbituric acid reaction²¹ to develop colour after elution of the sample from an anion exchange resin column. Each sugar analysis required about 25 μg of glycoprotein, except that 150 μg was used for the determination of fucose. All sugar measurements were made in the range of 5-15 nmol. No corrections were made for destruction of sugars during acid hydrolysis.

value of 75,000 had been assigned previously¹³. Although radioactive fucose has been shown to incorporate rapidly into glycoproteins of RSV¹⁰, chemical analysis shows a relatively small content of fucose.

Up to 45% of the sugar residues could be removed by digestion with glycosidases. Table 3 shows the release of sugars by α -neuraminidase, β -galactosidase and β -N-acetylhexosaminidase, incubated separately and in combinations. All the sialic acid was released by neuraminidase. β -Galactosidase alone released 25% of the galactose, suggesting that some galactose residues are at terminal positions. After removal of sialic acid most remaining galactose residues were susceptible to galactosidase; about one additional mole was released per mole of sialic acid cleaved. Very little N-acetylglucosamine was released from intact g2 by β -N-acetylhexosaminidase. When neuraminidase and galactosidase were included in the incubation, nearly 50% of the N-acetylglucosamine was released—an amount about equal to the total galactose content of g2.

These results suggest that the structure of the terminal region of the carbohydrate unit consists largely of sequences: sialic acid \rightarrow galactose \rightarrow N-acetylglucosamine \rightarrow , and galactose \rightarrow N-acetylglucosamine \rightarrow . The same sequences have been found in many soluble vertebrate glycoproteins¹. Recently, rabbit interferon was shown to have sialic acid \rightarrow galactose \rightarrow sequence²³. The positions of mannose and the other glucosamine residues in the g2 glycoprotein have yet to be determined. The major glycoprotein described here corresponds to the knob projections in avian RNA tumour viruses², and seems to perform an important function as it may recognise and interact with the receptor sites of

Fig. 2 Polyacrylamide gel electrophoresis of the purified glycoprotein from Bio-Gel P-150 chromatography. Aliquots of the combined fractions from Fig. 1C were electrophoresed alone (bottom) or together with horse heart cytochrome c (top) in SDS gels. The mobility of cytochrome c was about 3.4 times faster than that of the g2 glycoprotein.

TABLE 3 Glycosidase digestions of the g2 glycoprotein.

Sugar measured	Enzyme treatment	μ mol released per mg peptide	% Release
Sialic acid	α -Neuraminidase	0.43	107
Galactose	β -Galactosidase	0.15	23
	β -Galactosidase + α -Neuraminidase	0.59	92
Glucosamine	β -Hexosaminidase	0.05	4
	β -Hexosaminidase + β -Galactosidase + α -Neuraminidase	0.64	47

Neuraminidase (*C. perfringens*) was obtained from Boehringer Mannheim. Digestion was carried out overnight at 37°C in 0.03 M potassium acetate, pH 4.5, containing 0.03% bovine serum albumin (BSA), with an enzyme to substrate ratio of 1:15. Under these conditions, sialic acid was liberated completely from α -acid glycoprotein. Aliquots of digestion mixture were assayed directly by the autoanalytical method (see Table 2). Jack bean β -galactosidase²² was obtained from Dr Y. T. Li. Digestion was carried out at 23°C for 3 d in 0.03 M potassium acetate, pH 4.0, containing 0.03% BSA, a trace of thymol as preservative, and 1.5 enzyme units per 100 μ g of glycoprotein. Digestion was monitored at 24-h intervals by direct application of aliquots of mixture to the autoanalytical system. The enzyme remained active during the entire incubation period. Jack bean β -N-acetylhexosaminidase²² was obtained from Dr Y. T. Li. Digestion was carried out at 23°C for 3 d in 0.06 M sodium citrate, pH 4.0, containing 0.02% BSA, a trace of thymol, and 25 units of enzyme per 100 μ g of glycoprotein. Digestion was monitored at 24-h intervals. The liberated N-acetylglucosamine was deproteinized with Dowex 50, deacetylated with 4 N HCl for 6 h at 100°C, and assayed as free glucosamine using the autoanalytical system. In experiments where combinations of enzymes were used, the incubation conditions for all enzymes were those appropriate for the first listed enzyme.

permissive host cells during the first step of a successful infection. Involvements of carbohydrate moieties during cellular interactions have been hypothesized²⁴, and there is some supporting evidence²⁵. The interplay between cell surface sialic acids and viral neuraminidase is now well understood²⁶. It will be interesting to compare sugar sequences and amino acid compositions of glycoproteins from various strains of RSV. These glycoproteins are now being isolated and characterised.

Early changes in the kidneys of BALB/c mice infected with lactic dehydrogenase virus

Mice infected with lactic dehydrogenase virus (LDV) have lifelong viraemia and raised plasma enzyme levels¹⁻⁴. In spite of rapid and prolonged virus replication, probably in the macrophages, only minor histological changes in lymphoid organs are reported⁵. Antibodies are produced⁶ and complexes are said to be deposited in the glomerular capillary walls but only minimal glomerulonephritis results^{7,8}.

Electron microscopic studies of liver, spleen and lymph nodes failed to show any changes, but in the kidneys of BALB/c mice there were striking changes as early as 24 h after infection, which persisted for at least 3 months. They were confined to the glomeruli and consisted of cytoplasmic endothelial swelling and darkly staining deposit between endothelial cells and basement membrane. There were no basement membrane changes or foot process adhesions. The electron micrograph (Fig. 1) of a glomerulus from an animal 12 h after infection shows markedly swollen endothelial cells filling the lumen of the glomerular capillaries. A dark exudate is present between many endothelial cells and the basement membranes, which are normal.

FIG. 1 Electron micrograph of a section of a glomerulus 12h after infection with LDV (X1,880).

TABLE 1 Effect of nephrectomy on replication of lactic dehydrogenase virus.

	Blood virus titre (log ₁₀ ID ₅₀ ml ⁻¹)	
	4 h and 24 h after infection	
Intact	3.5	8.0
Nephrectomised 2 h after infection		3.0
Nephrectomised 4 h after infection		6.0

All the mice were injected intravenously with the same dose of virus and the figures given are the means of three titrations using two mice at each 10-fold dilution.

The early changes in the endothelial cells indicate that the virus might be replicating in them. To investigate this, the effect of bilateral nephrectomy on the level of infectivity of LDV 24 h after infection was measured. As shown in Table 1, total nephrectomy 2 h after infection reduced the level of viraemia at 24 h. The nephrectomised mice seem normal after the operation but by 24 h they were very ill. It was therefore likely that the reduced level of viraemia in the nephrectomised mice was due to toxæmia rather than removal of a site of virus production. This view was supported by the observation that nephrectomy had less effect on virus levels if delayed for 4 h after infection, although no new virus enters the blood until 5 to 6 h after infection.

Unlike other authors^{7,8} we have not found glomerular immune complex deposition in LDV-infected BALB/c mice in the first 3 months, so the changes in the kidneys seen by electron microscopy cannot be related to these deposits. It is possible that the glomerular lesions described here prevent the deposition of immune complexes in the glomeruli. Infection with LDV reduces the severity of spontaneous glomerulonephritis in New Zealand mice⁹. This may be due to reduced levels of antibody⁹ but perhaps the changes produced in the glomerular capillary endothelium by the virus play some part. It would be interesting to know how infection with LDV would affect the development of nephritis resulting from chronic infection with lymphocytic choriomeningitis virus.

The study was in part supported by a grant from the Leukaemia Research Fund.

Reticulocyte DNA polymerase

DNA polymerase has been isolated from the cytoplasm of several mammalian tissues as well as several cell lines in culture¹⁻⁸. This has been puzzling because DNA replication and repair are processes generally believed to be restricted to the nucleus, where chromatin is located. It has been suggested that cytoplasmic DNA polymerase is newly synthesised, not yet having been transported to the nucleus⁹ or that it could have leaked from the nucleus during cell disruption^{10,11}. Investigation of possible functions of a DNA polymerase in the cytoplasm have been inhibited by the possibility that the cytoplasmic location of this enzyme is either artefactual or trivial. To demonstrate that this is not so, we have investigated the presence of the enzyme in the reticulocyte, which is an anucleate cell. We wish to report here the purification and characterisation of a DNA polymerase from rabbit reticulocytes, and compare its properties with those of the DNA polymerase purified from the cytoplasm of immature erythroblasts of bone marrow, the precursor of the reticulocyte.

Reticulocytosis was induced by the procedure of Borsook *et al.*¹² New Zealand rabbits (4-6 pounds) were given four daily injections of 1.0 ml of 2.5% neutralised phenylhydrazine. Three days later they were bled by cardiac puncture. Whole blood contained more than 80% reticulocytes.

Washed reticulocytes were prepared by repeated suspension in 130 mM NaCl, 5.0 mM KCl and 7.4 mM MgCl₂, centrifugation at 2,000 *g*, and removal of the buffy coat (nucleated cells and platelets). Washed reticulocyte preparations usually contained less than 0.5% nucleated cells, of which approximately 50% were immature red cells. Comparison of enzyme preparations from washed reticulocytes and from buffy coat cells indicated that enzyme activity is proportional to total cell number and not to the number of nucleated cells.

The packed reticulocytes from 400 ml of whole blood were lysed by addition of 250 ml lysis buffer (10 mM Tris-HCl, pH 7.4, 15 mM KCl and 5 mM 2-mercaptoethanol) followed by gentle stirring for 20 min at 0° C. Cell debris was removed by centrifugation at 30,000*g* for 15 min. The supernatant was made 5.0 mM in MgCl₂ and 0.5 M in KCl and the polysome fraction was removed by centrifugation at 78,000*g* for 120 min. The supernatant was made 40% saturated in (NH₄)₂SO₄ by addition of solid (NH₄)₂SO₄ over 2 h. The (NH₄)₂SO₄ precipitate was collected by centrifugation at 30,000*g* for 15 min, suspended in TSED (50 mM Tris-HCl, pH 7.8, 1.0 mM dithiothreitol, 1.0 mM EDTA and 0.25 M sucrose), and dialysed against 1 l of TSED for 3 h with one change of buffer. The dialysed extract was applied to a phosphocellulose column (2.3 × 18 cm), previously equilibrated with TSED, and washed with the same buffer. A linear gradient of 0 to 1.0 M KCl in TSED with a combined volume of 300 ml was applied and 3 ml fractions were collected. DNA polymerase activity was eluted at 0.25 M KCl. The phosphocellulose fractions with activity were pooled and dialysed against 1 l of TGED (50 mM Tris-HCl, pH 7.8, 1.0 mM dithiothreitol, 1.0 mM EDTA, 25% glycerol) for 4 h with one change of buffer. The dialysed enzyme was applied to a DEAE-Sephadex A-50 column (1.8 × 9 cm), previously equilibrated with TGED, and washed with the same buffer. DNA polymerase was eluted stepwise with TGED containing 0.25 M KCl. A summary of the enzyme purification is shown in Table 1. As haem has been found to be a potent inhibitor of the enzyme, it is possible that the low activity of the crude enzyme fractions is due to inhibition by haem. The overall purification obtained was 2,400-fold with a yield of 73%.

In contrast to the cytoplasmic DNA polymerase of erythroblasts which is associated with the microsomes and

The standard assay mixture contained in a final volume of 0.25 ml: 40 mM HEPES (N-2-hydroxyethylpiperazine-N'-2'-ethanesulphonic acid) buffer, pH 7.0, 0.4 mM MnCl₂, 60 mM (NH₄)₂SO₄, 0.16 mM each dATP, dGTP and dCTP, 0.004 mM ³H-dTTP, 2,000 μCi μmol, 20 μg activated calf thymus DNA and 5–10 μg enzyme. The reaction mixture was incubated for 15 min at 37°C and stopped by the addition of 2 ml of cold 5% trichloroacetic acid. The precipitate was collected on a glass fibre filter (Whatman GF/C) and washed with trichloroacetic acid and ethanol. The filter was dried and counted in a liquid scintillation counter. Activated calf thymus DNA was prepared as described by Aposhian and Kornberg¹³. One unit of activity is defined as the amount of enzyme which incorporates one picomole of dTMP in 15 min of incubation at 37°C.

is only solubilised in the presence of high salt concentrations, most of the reticulocyte enzyme is present in the cytosol even at low ionic strength.

The requirements for the synthesis of DNA are shown in Table 2. There is an absolute requirement for a template and a divalent cation. The rate of DNA synthesis is stimulated about three-fold by monovalent cation and about 10%

TABLE 2 Requirements for DNA synthesis

Reaction conditions	³ H-dTMP incorporated (pmol)	% Control
Complete	13.3	100
—dithiothreitol	12.0	90
—divalent cation	0.5	4
—monovalent cation	4.0	30
—template	0.4	3
—enzyme	—	—
—dATP	3.9	30
—dATP, dCTP, dGTP	2.3	17

Incubation conditions were the same as described in Table 1 except that the individual components were omitted as indicated.

by dithiothreitol. All four deoxyribonucleoside triphosphates are required for optimal activity and in the absence of one or more deoxyribonucleoside triphosphates there is a substantial decrease in the rate of dTMP incorporation. This has also been observed with other mammalian DNA polymerases when one (or more) deoxyribonucleoside triphosphate was omitted^{6,14}.

The divalent cation requirement can be satisfied by either Mn²⁺ or Mg²⁺, although at different concentrations (Fig. 1),

TABLE 3 Template specificity

Template	Concentration (μg per assay)	³ H-dTMP incorporated (pmol)

poly (dA)	2	0.8
poly (A)·poly (U)	10	0.2
poly (A)	10	0.2

Reaction conditions were as described in Table 1 except for the addition of templates as indicated.

the optimal concentration of MgCl₂ being ten times that of MnCl₂. The effect of monovalent cation concentration is shown in Fig. 2. Although all the monovalent cations tested stimulate the rate of DNA synthesis, KCl gives the greatest stimulation, and NH₄Cl and NaCl are less effective. The optimal concentration for all three monovalent cations is 100 mM at pH 7.0. Both the reticulocyte enzyme and the erythroblast enzymes can use either Mn²⁺ or Mg²⁺ as divalent cation and both are stimulated optimally by 100 mM KCl.

At optimal conditions of pH and ionic strength, the reticulocyte DNA polymerase sediments predominantly at 8S, with a smaller peak of activity at 11S (Fig. 3). This is also the case with the erythroblast enzyme, which has been shown to dissociate from an 11S dimer to an 8S monomer under conditions of salt activation⁷. No DNA polymerase activity sedimenting at 3.4S has been detected. Chang and Bollum have found a high molecular weight DNA polymerase of 6–8S and a low molecular weight DNA polymerase of 3.4S in the cytoplasm of bone marrow and several other tissues, while only the 3.4S DNA polymerase

Fig. 1 Effect of divalent cations. Assay conditions were as in Table 1 except for the concentrations of divalent cations. MgCl₂ (●) and MnCl₂ (○).

FIG. 2 Effect of monovalent cations. Reaction conditions were as in Table 1 except for the salt concentration. NH₄Cl (●), KCl (▲) and NaCl (○).

was present in the nuclei of these tissues^{5,15}. The absence of a 3.4S DNA polymerase in reticulocytes is consistent with their lack of a nucleus.

The ability of several DNAs, RNAs and synthetic polynucleotides to serve as templates for the reticulocyte DNA polymerase was tested (Table 3). As is the case with the erythroblast cytoplasmic DNA polymerase, activated calf thymus DNA was the best template for the reticulocyte enzymes. However, in contrast to the erythroblast enzyme, poly d(A-T) the alternating copolymer of deoxyadenylate and deoxythymidylate, was less than half as active as activated calf thymus DNA⁷. Double stranded synthetic DNAs such as poly(dA)·poly(dT), or DNA·RNA hybrids were either inactive or very poor templates, as were single stranded RNAs or single stranded homopolymers such as poly(dA) or poly(A). Native calf thymus DNA was less effective as a template than activated calf thymus DNA, suggesting that the reticulocyte enzyme, as well as the erythroblast enzyme, cannot initiate DNA synthesis in the absence of a primer.

Similar to the erythroblast enzyme⁷, the reticulocyte DNA polymerase is markedly inhibited by the rifamycin derivative AF/013 which has also been shown to inhibit the nuclear DNA-dependent RNA polymerases¹⁶⁻¹⁸ as well as the viral RNA-dependent DNA polymerase¹⁸. The synthesis of DNA is also very sensitive to the intercalating dye ethidium bromide, being 50% inhibited at 8 $\mu\text{g ml}^{-1}$. Of particular interest is the inhibitory effect of haem which has been implicated in the control of haemoglobin synthesis in reticulocytes at the translational level^{19,20}. The concentration of haem that completely inhibits the cytoplasmic DNA polymerase (10^{-5} M) is the same as that reported to stimulate globin synthesis optimally²¹.

As with the erythroblast cytoplasmic DNA polymerase⁸, the synthesis of DNA with the reticulocyte enzyme is stimulated by ribonucleoside and deoxyribonucleoside triphosphates. The greatest degree of stimulation is seen with ATP which stimulates the rate of DNA synthesis 3.5-fold, while GTP, UTP and CTP stimulate 2.5 to 3-fold. The α , β - and γ -methylene analogues of ATP are also stimulatory, as is ADP and α , β -methylene ADP. However, 3'-AMP and

5'-AMP have no effect on the reaction. We have previously shown that the erythroblast cytoplasmic DNA polymerase is activated by ribonucleoside diphosphates and triphosphates and that the effect of these activators is to increase the V_{max} of the enzyme rather than to lower the K_m values for the substrates⁸. Furthermore, it has been shown that the mechanism of ATP activation involves the dissociation of the enzyme from an inactive 11.6S dimer to an active 8S monomer. Presumably the reticulocyte enzyme responds to nucleotide activation in the same way. The enzyme isolated from reticulocytes is very similar in its properties to that isolated from the cytoplasm of the nucleated erythroblasts of bone marrow; one difference being that most of the reticulocyte enzyme is not associated with the microsomes even at low ionic strength.

FIG. 3 Sucrose density gradient analysis of reticulocyte DNA polymerase. DNA polymerase was dialysed for 4 h against 5% sucrose buffer containing 10 mM HEPES buffer, pH 7, 1.6 mM MnCl₂, 1.0 mM dithiothreitol and 40 mM KCl. A sample of 0.2 ml of enzyme solution containing 320 μg of protein was layered on a 5–20% sucrose gradient and sedimentation was carried out in a Spinco SW 39 rotor for 15 h at 37,000 r.p.m. at 2°–4° C. Simultaneously 4S tRNA was sedimented as a marker. Thirty-eight equal fractions were collected from the bottom of the tubes and assayed for DNA polymerase activity.

The purification of DNA polymerase from reticulocytes is good evidence that this is in fact a cytoplasmic enzyme. However, the exact role of the cytoplasmic DNA polymerase is not known. It has been proposed that this enzyme is involved in processes of cellular differentiation and gene amplification⁷. This is particularly relevant in an erythroid cell where a large quantity of haemoglobin is synthesised in a relatively short time and no evidence of nuclear gene amplification for this protein has been demonstrated^{22,23}. It is our hypothesis that cytoplasmic DNA and RNA polymerases are involved in the regulation of expression and amplification of genetic information^{7,24}.

The induction of tumour immunity in mice using glutaraldehyde-treated tumour cells

INDUCING immunity to tumours presents problems similar to those of inducing immunity to infectious microorganisms—the presentation of the agent in an antigenic but non-infectious form. Two approaches have been used to render syngeneic tumour cells non-infectious, lethal irradiation¹ and treatment with chemically reactive groups such as iodoacetamide^{2,3}. These treatments leave the cell metabolising but incapable of division.

Here we demonstrate the use of glutaraldehyde-treated cells for the induction of immunity in syngeneic hosts. Glutaraldehyde solution contains polymeric α and β unsaturated aldehydes resulting from aldol condensation. These react rapidly with protein amino groups in mild conditions and cross link the protein molecules. The modification is irreversible and does not disorder the crystal structure⁴. For these reasons glutaraldehyde has found wide application as a fixative for electron microscopy and X-ray diffraction.

A methyl-cholanthrene-induced BALB/c tumour (Meth A)⁵ was passaged in BALB/c mice by intraperitoneal (i.p.) inoculation. This transplantable tumour is highly infectious in syngeneic animals and a dose as low as 10^8 i.p. will cause ascites and eventual death of the animals. Cells collected from the peritoneum were used for immunisation and challenge. Cells for immunisation were washed in phosphate-buffered saline (PBS), pH 7.0, and made up to 10^8 ml⁻¹. An equal volume of 0.25% glutaraldehyde (Taab Laboratories, Reading, England) in PBS was added. After 10 to 15 min at

22° C, the cells were washed three times by centrifugation. BALB/c female mice were inoculated i.p. with a single injection of 5×10^7 glutaraldehyde-treated cells. Age matched non-immunised mice were kept as controls. After 2 weeks, both groups were challenged i.p. with live tumour cells. Cages containing the different groups were coded before challenge so that the operator could not identify the groups during injection or subsequent inspections.

Non-immunised control mice (Table 1) challenged with 10^8 tumour cells survived for approximately 20 d. Immunised mice were completely protected against this challenge (experiments I, II, III, IV) but not against challenge by 10^6 tumour cells (experiments I and III). In contrast, mice immunised with the same number of irradiated cells showed less protection (experiment IV). In one experiment (II) the glutaraldehyde-treated cells were stored for 2 weeks at 4° C before immunisation. These cells gave similar full protection against the challenge. Mice left for 27 d between immunisation and challenge showed only partial protection (experiment V), indicating that immunity was decreasing at that time.

Preliminary data with a second tumour (a mammary tumour which arose spontaneously in our colony) corroborates these findings. Furthermore, we have found that protection against a higher challenge dose can be achieved with multiple immunisation, whereas mice injected with a similar number of glutaraldehyde-treated syngeneic spleen cells showed no protection. This data will be presented in a subsequent publication.

Two factors might be operating in producing this immunity. First, glutaraldehyde may be preserving the tumour antigenicity and, second, the chemical modification of the proteins may be producing an enhanced cellular immunity at the expense of the humoral response. This phenomenon has been studied in some detail with protein antigens^{6,7}. The implication is that the development of enhancing antibody may be minimal. Further experiments are in progress to study the mechanisms involved.

TABLE 1. The protective effect of glutaraldehyde-treated tumour cells on subsequent challenge with live tumour cells.

Immunisation dose of glutaraldehyde-treated tumour cells	Time before challenge (d)	Challenge dose of live tumour cells (i.p.)	Survivals*			
			Day 0	10	20	30
Experiment I						
5×10^7	14	10^8	5	5	5	5†
Control		10^8	5	5	2	0
Experiment II

(stored cells)†						
Control		10^8	5	5	0	0
Experiment III						
5×10^7	14	10^8	5	5	5	5
		10^6	5	5	0	0
Control		10^8	5	5	1	0
		10^6	5	5	0	0
Experiment IV						
5×10^7	14	10^8	5	5	3	1
(irradiated cells)‡						
5×10^7	14	10^8	5	5	5	5
Control		10^8	5	5	0	0
Experiment V						
5×10^7	27	10^8	4	4	2	2
Control		10^8	5	4	3	0

* Mice developing tumours were usually recognisable before day 10, but only deaths are recorded in this table.

† Surviving mice were observed up to 60 d. No further tumours developed. This group was re-challenged on day 57 with 10^8 tumour cells i.p. None survived.

‡ Treated cells stored for 2 weeks at 4° before immunisation.

§ Cells were washed and resuspended at 5×10^7 ml⁻¹ in PBS immediately before subjecting to 4000 rads γ irradiation from a ⁶⁰Co source.

These preliminary results show that tumour immunity can be induced using glutaraldehyde-treated tumour cells. Apart from the possibly greater immunogenicity, compared with irradiated cells, the treatment is simple and the cells are non-viable. Furthermore, it may be possible to store the treated cells for repeated immunisation. By comparison with previously published data^{2,3,8}, the high degree of protection achieved is sufficiently encouraging to justify experiments with other tumours and other species. If the efficacy can be substantiated the procedure could have advantages in the investigation of tumour immunotherapy in man.

Fluctuations and distribution of measles virus antigens in chronically infected cells

THE question of chronic measles virus infections in human central nervous system disease has become increasingly important. In subacute sclerosing panencephalitis the role of measles virus has been established¹. In multiple sclerosis the role of measles is less clear although seemingly implicated². It has been suggested that a virus-induced immunopathological process may be involved, initiated by the incorporation of viral antigens into the surface membrane of cells³. The study of measles envelope antigens on the surface of cells in an *in vitro* model is therefore of interest. Here we report the quantitative fluctuations of measles virus antigens at the cell surface in chronically infected cell

FIG. 1 Fluctuations of membrane immunofluorescence, haemadsorption and extracellular infectivity. ○—○, Immunofluorescence with anti-HL serum; □—□, immunofluorescence with anti-HA serum; ■—■, haemadsorption; △··△, infectivity TCID₅₀ titres.

FIG. 2 Fluctuations of surface antigen expression in cells chronically infected with measles virus. Membrane immunofluorescence specific for HL (○) and HA (□).

cultures measured by haemadsorption and indirect membrane immunofluorescence.

A carrier cell line of the Edmonston strain of measles virus in a human heteroploid lung cell line (Lu 106) was used⁴. The cells were maintained for 24 h in Eagle's minimum essential medium (E-MEM) containing 1% L-glutamine, penicillin and streptomycin and 1% calf serum to synchronise cell division before the initiation of individual experiments. Vero cells lytically infected with measles virus were used as controls to test the reliability of the serum, conjugate, and staining technique. Cells were trypsinised in 0.1% trypsin-0.02% versene buffer and suspended in 2% calf serum in E-MEM and 30,000 cells ml⁻¹ were placed on coverslips (10 × 40 mm) within sealed Leighton tubes at 37° C. Uninfected Lu 106 cells were used as controls. The cell cultures approached a monolayer by the end of two weeks. Coverslips were taken for examination every 4 h for the first 12 h and at 24 h intervals for the first 4 d and then on three alternate days each week. A parallel series of extracellular samples were collected for determination of infectivity titres in roller tubes of Vero cells. From serial ten-fold dilutions 0.1 ml samples were taken and inoculated into three tubes per dilution. Final readings were made 14 d after inoculation and the tissue culture infectious dose causing specific cytopathic effects in 50% of the tubes (TCID₅₀) was calculated. Haemadsorption was carried out by washing with phosphate-buffered physiological saline (PBS) without Mg²⁺ and Ca²⁺ and addition of 0.1% African green monkey cells. After adsorption at room temperature for 1 h the coverslips were washed twice with PBS and then examined by light microscopy.

Antisera were prepared by hyperimmunising rabbits (using Freund's complete adjuvant and an intravenous booster after 5 week) with purified whole virus from Vero cells, small particle haemagglutinin (HA) (ref. 5), and virus particles from which surface projections had been removed by treatment with 0.004% trypsin. This treatment removes HA projections but leaves some envelope-associated haemolysin (HL) (Norrby, to be published). Sera were tested by haemagglutination inhibition (HI) and haemolysin inhibition (HLI) tests as described previously⁶. Anti-HA serum had an HI antibody titre of 5,000, but no HLI antibodies demonstrable after removal of HI antibodies by absorption with Tween 80-ether antigen⁶. Anti-HL serum had an HLI titre of 320 and an HI titre of less than 5. Rabbit control serum against uninfected Vero cells was prepared. Before use in immunofluorescence measurements sera were absorbed with non-infected Vero cells.

For membrane immunofluorescence measurements coverslips were washed twice in PBS without Ca²⁺ and Mg²⁺ and incubated with specific antiserum for 30 min at room

temperature. Antiserum was removed by washing twice in PBS; sheep anti-rabbit gamma globulin conjugated to fluorescein isothiocyanate (FITC) (National Bacteriological Laboratory, Stockholm, Sweden) was added for 30 min. After two additional washings in PBS, coverslips were mounted in buffered glycerol on glass slides. The slides were examined immediately with a Zeiss fluorescence microscope. After storage at 4° C a second blind reading was performed by another person at the end of the experiment.

The number of cells showing intense fluorescence was estimated. A grading from + to ++++ was used; + representing 10–25%, ++ 25–50%, +++ 50–75%, ++++ more than 75%. Periodic fluctuations in the numbers of cells displaying membrane HA occurred in all four experiments (Figs 1 and 2). During the first 2–4 d the number of positive cells increased to a maximum of ++ to ++++. Thereafter fluorescence disappeared and remained absent for 1–2 d. Fluorescence then reappeared independently of growth medium changes. During the 2 week observation period one more cycle of disappearance and reappearance was encountered in three experiments.

Membrane fluorescence specific for HL antigen fluctuated in two experiments (Figs 1 and 2). It remained absent throughout the other two experiments despite variations of the HA antigen. HL antigen expression was occasionally found in the absence of HA antigen (Fig. 2).

The titre of extracellular infectious virus varied but did not show a distinct correlation with presence or absence of membrane antigens as measured by immunofluorescence (Fig. 1). Intracellular antigen and haemadsorption fluctuated only a little and never occurred in fewer than 75% of cells. Haemadsorption therefore was a more sensitive indicator of surface measles antigen than membrane immunofluorescence.

A polar distribution of antigen (capping) commonly occurred in single cells or in cells appearing to undergo division (Fig. 3a and b). In Fig. 3b there is polar fluorescence at opposite ends of what may be a cell in mitosis. In other cells the discontinuous membrane immunofluorescence was most common (Fig. 4a and b). The relatively smaller syncytium in *a* displays a more intense membrane immunofluorescence than the syncytium in *b*. This was generally true.

Several membrane antigens have the capacity to redistribute^{7–9}. Marcus found viral protein at one end of cells by haemadsorption in NDV-infected cells¹⁰. Capping of viral antigen might be of some interest with reference to a possible occurrence of antigenic modulation⁹.

Various factors such as cell growth^{11,12}, phases of the cell cycle^{11,12}, energy generating system¹³ and pinocytosis of antigen-antibody complexes after capping⁹, have been

FIG. 3 *a* and *b*. Capping of measles virus HA antigen demonstrated by indirect membrane immunofluorescence. Magnification $\times 930$.

FIG. 4 Membrane antigens on single cells and syncytia in a culture chronically infected with measles virus, demonstrated by the indirect immunofluorescence technique using an anti-'whole' virus serum. Magnification $\times 750$.

found to cause fluctuating expression of different surface antigens. In a cell line chronically infected with virus, factors such as autointerference or interferon production^{14,15} may also be of importance. It has been observed (A. E., to be published) that carrier Lu 106 cells display a varying sensitivity to measles virus-specific cytotoxic antibodies. This may relate to the variable expression of membrane antigen as shown by immunofluorescence.

In multiple sclerosis the pathogenesis and aetiology of the disease is not known, but it is possible that it represents a chronic infection and that the exacerbations and remissions characteristic of the disease are the result of irregular expression of virus-specific antigens in myelin membranes and an immunological attack on these antigens.

Dietary regulation of brain tryptophan metabolism by plasma ratio of free tryptophan and neutral amino acids in humans

CHANGES in brain tryptophan (Trp) associated with feeding are relevant to serotonin (5-hydroxytryptamine, 5-HT)-mediated function, because in the brain Trp levels modulate 5-HT synthesis¹. Using rodents, some investigators²⁻⁵ have confirmed our observations^{6,7} that after ingestion of balanced diets plasma Trp increases but brain Trp decreases or is unchanged. Other such dissociations between plasma and brain Trp have been observed during fasting, and after eating in hypophysectomised rats, indicating that the changes are not secondary to stress or pituitary mechanisms⁷. The dissociation is also independent of diurnal or nocturnal variations in plasma Trp^{4,7}, but there is no explanation for it.

On the other hand, ingestion of pure carbohydrate (CHO) diets⁸⁻¹⁰, and injection of Trp⁵ and drugs that affect 5-HT metabolism¹¹ increase both total plasma and brain Trp. This

led to the hypothesis that levels of total plasma Trp reflect levels of brain Trp⁸. The hypothesis has been challenged by evidence that injections of Trp increase free plasma much more than total plasma Trp⁵.

A further challenge is the report that CHO diets increase total plasma and brain Trp, but decrease free plasma Trp¹⁰. Some drugs that increase brain Trp and 5-HT metabolism do not increase free plasma Trp¹². Furthermore, transport of Trp from plasma to brain depends on levels of competing plasma amino acids⁹ and on the ratio between total plasma Trp and neutral amino acids (NAA) in plasma⁹. So far, there is general agreement that after ingestion of balanced diets^{2,3,5} or CHO diets^{10,13}, free plasma Trp is decreased, and total and bound plasma Trp are increased.

Tryptophan is an essential amino acid, normally binding to albumin in plasma¹⁴. Displacement of Trp from the binding site in the albumin molecule by free fatty acids (NEFA)^{2,3,10}, and by drugs that decrease plasma Trp but increase brain Trp^{11,15}, is a suggested cause of plasma-brain Trp dissociations. It has been speculated that CHO and insulin increase the albumin-binding of Trp by decreasing the extent of saturation of albumin with NEFA¹⁰. Decreases of plasma NEFA after ingestion of balanced diets or insulin and CHO diets are well known¹⁶. Mobilisation of NEFA can also be influenced by concentrations of plasma triglycerides of hepatic or dietary origin¹⁶. A role of NEFA in controlling food intake has been postulated¹⁷, but whether plasma Trp (free or bound) is concerned with the control of food intake remains to be seen. In humans, injection of insulin increases total plasma Trp and decreases plasma NAA¹⁸, and CHO ingestion reduces plasma NEFA and free plasma Trp¹³.

We have investigated the mechanisms mediating plasma-brain Trp dissociations and looked for similar relationships between total, bound and free plasma Trp and cerebrospinal fluid (CSF) in human subjects after intake of a balanced diet.

Twenty-nine subjects with Parkinson's disease, Huntington's chorea or related neurological disorders volunteered for diagnostic studies of monoamine metabolism. They were fasting and recumbent in bed for 12 h before CSF was drawn by lumbar puncture (at 1000 h), and samples were mixed with 2% ascorbic acid and cooled to -20°C. Blood was drawn by venipuncture and centrifuged. The plasma was stored at -20°C. This procedure was repeated at 1600 h. Between sampling all subjects remained in bed; nine fasted all the

Total plasma Trp was isolated¹⁹ and bound and free (ultrafiltrate) plasma Trp were separated as before²⁰. CSF-Trp and the main metabolite of 5-HT in CSF, 5-hydroxyindoleacetic acid (5-HIAA), were separated in a Dowex 50, Na⁺ resin²¹.

Plasma NAA (valine, isoleucine, leucine, tyrosine and phenylalanine) were separated by column chromatography with a Beckman model 120 C, amino acid analyzer. The plasma ratios between Trp (total, bound or free) and NAA were obtained by dividing Trp in plasma by the sum of the five plasma NAA⁹. Trp and 5-HIAA were determined fluorometrically as described elsewhere^{7,11}. Total serum protein, albumin, and triglycerides were determined by the clinical laboratory of NIH. Statistical analyses were done using paired Student's *t* tests and linear correlations²².

time; at 1200 h fourteen ate a random balanced diet, hospital lunch (diet *a*, 25 g protein, 25 g fats, 55 g carbohydrates, totalling 545 calories); six received equivalent calories in the form of 60 g roast turkey, 100 g steamed rice, 20 g bread, 10 g butter, 100 g unsweetened apple sauce and 240 ml of whole milk (diet *b*) to control for the randomness of the diet. As Table 1 shows all subjects who received diet *a* and diet *b* showed statistically significant changes between the fasting (1000 h) and postprandial (1600 h) samples: postprandial levels of total and bound plasma Trp increased whereas free plasma Trp levels were consistently decreased. Postprandial levels of CSF-Trp and CSF-5-HIAA were also decreased in the 1600 h samples. Significant negative correlations between total or bound plasma Trp and CSF-Trp or CSF-5-HIAA were obtained regardless of diet and it is unlikely that these changes are due to a diet artefact. Positive non-significant correlations between free plasma Trp and CSF-Trp or CSF-5-HIAA were obtained. If Table 1 is interpreted without considering the food intake status of the subjects, a negative correlation between total plasma Trp and CSF-Trp or CSF-5-HIAA is still obtained during the two samplings, but the correlations between free plasma Trp and CSF-Trp and CSF-5-HIAA were only positive during the fasting (1000 h) samplings. The percentage changes during the postprandial period in total and bound plasma Trp and CSF-5-HIAA were greater with diet *b*, whereas they were greater for free plasma Trp with diet *a*. In nine subjects who fasted throughout the test, no significant postprandial changes in CSF-5-HIAA were observed between the two samples (difference: 0.70 ± 3.5 ng/ml $^{-1}$, $P > 0.05$). CSF-Trp or total plasma Trp was not measured in these subjects, but it is also unlikely that the postprandial changes in total, bound, and free plasma Trp and CSF-Trp are due to diurnal variations^{4,7}.

In subjects eating diet *b*, plasma levels of valine, isoleucine, leucine, tyrosine and phenylalanine increased significantly as illustrated (Table 2A). The greatest postprandial increments in plasma NAA were observed in isoleucine and leucine (61.6% and 59.8%, respectively), and the smallest in valine and phenylalanine fractions (32.7% and 30.0%, respectively). As Table 2B shows, the postprandial ratio of total plasma Trp to NAA was not changed, whereas the postprandial ratio of free plasma Trp to NAA was reduced (-49.5%, $P < 0.01$). There was significant positive correlation between the ratio of free Trp to NAA and CSF-Trp or CSF-5-HIAA, but not between the ratio of total plasma Trp to NAA and CSF values.

Since Trp binds avidly to plasma albumin, an increase in this protein can influence the transport of this amino acid into brain. All subjects showed an increase in serum proteins and plasma albumin after feeding. Serum proteins were in-

creased from 6.70 ± 0.37 g per 100 ml to $7.05 \pm .40$ g per 100 ml. Serum albumin was increased from 3.86 ± 0.018 g per 100 ml to 4.04 ± 0.17 g per 100 ml. These increments in plasma albumin represent an increase in the availability of binding sites for plasma Trp. Although NEFA were not measured, it is well known that ingestion of balanced or CHO diets decreases plasma NEFA¹⁶. Measurements of the plasma triglycerides were considered more valuable, because diets rich in CHO produce significant increments in plasma triglycerides which influence the mobilisation of NEFA from fat and liver²³. All subjects developed a significant postprandial hypertriglyceridaemia. Serum triglycerides increased from 87.66 ± 10.80 mg per 100 ml to 136.00 ± 18.25 mg per 100 ml. The increment in dietary and liver triglycerides after feeding is probably responsible for the significant decrease in plasma NEFA, and hence may influence the albumin-binding of Trp by decreasing the extent of saturation of albumin by NEFA.

Determinations of precursors such as Trp, and metabolites of 5-HT such as 5-HIAA, in lumbar CSF have been used widely to estimate the metabolic state of 5-HT in the human central nervous system, where more direct measurements are impossible²⁴. There is abundant evidence that changes in lumbar CSF reflect changes in brain²⁵. It is now certain that lumbar CSF-5-HIAA does not all derive from the lumbar cord as reported by Bulat *et al.*²⁶, and using their experimental conditions it has been shown that 40% to 50% derives from brain 5-HIAA²⁷. It has also been estimated that in humans, 23% to 37% of the lumbar CSF-5-HIAA is derived from spinal 5-HIAA²⁸. The decrease of CSF-Trp and CSF-5-HIAA after feeding suggests that similar changes occur in the human brain. These facts suggest that the synthesis of brain 5-HT is decreased after ingestion of food in humans. In rodents balanced diets produce a decrease in the synthesis of 5-HT⁷. Our values of CSF-Trp and CSF-5-HIAA are within the range of values reported by others for human CSF²⁴.

There is general agreement that CHO or balanced diets increase plasma Trp (total and bound) and decrease free Trp and NEFA in the plasma^{8,10}. It is obvious that an increment in NAA is associated with a decrement in brain Trp, and that perhaps the ratios of total plasma Trp to NAA or free plasma Trp to NAA more accurately reflect the changes in brain Trp. In CHO diets we have found that although the levels of free plasma Trp were decreased, the ratio of free plasma Trp to NAA and the ratio of total plasma Trp to NAA were significantly increased ($P < 0.01$, manuscript in preparation). In humans, the ratio of total plasma Trp to NAA did not reflect changes in CSF-Trp or CSF-5-HIAA, whereas the ratio of free plasma Trp to NAA

was significantly correlated with changes in CSF values. This indicates that the ratio of free plasma Trp to NAA is the most important factor controlling the transport of plasma Trp into brain, and that this ratio reflects changes in brain Trp not reflected by either total plasma or free plasma Trp. This hypothesis does explain why CHO diets should increase brain Trp while routine diets should decrease it. In CHO diets free Trp to NAA is increased and in balanced diets the free Trp to NAA is decreased. Further experimentation will be necessary to establish definitively the generality of this new hypothesis.

Localisation of phenylethanolamine N-methyl transferase in the rat brain nuclei

THE conversion of noradrenaline to adrenaline is catalysed by phenylethanolamine N-methyl transferase (PNMT, EC 2.1.1)^{1,2}, which is highly localised in the adrenal medulla. Small amounts of PNMT-like enzyme³⁻⁵ and adrenaline^{6,7} have been detected in the central nervous system, and we

have now been able to study the distribution of the enzyme in specific nuclei of the rat brain. This has been made possible by the development of a technique for the dissection of small areas and individual nuclei⁸ of the brain, and the availability of a sensitive assay for the measurement of PNMT. Our findings suggest that adrenaline may serve as a neurotransmitter in the central nervous system.

Sprague-Dawley male rats (200–250 g) were killed by decapitation, and their brains were removed immediately and frozen on dry ice. Frontal serial sections 300 μ m thick were cut from the border between the spinal cord and the medulla oblongata, at the level of the pyramidal decussation, as far rostral as the level of the anterior commissure. Regions rich in catecholamine-containing cell bodies were removed under stereomicroscopic control⁸ as follows. The A1 region⁹ (equivalent to the C1 region of Hökfelt *et al.*¹⁰), was located in the lateral reticular nucleus of the medulla oblongata, between the pyramidal tract and the tractus spinalis nucleus trigemini just under the ventral surface of the medulla oblongata. (Details of the various dissections mentioned here will be published elsewhere.) The A2 region (probably the same as the C2 region of Hökfelt *et al.*¹⁰) contains catecholamine cell bodies at the level of the region of the vagal nuclei (nucleus commissuralis, nucleus originis dorsalis vagi, nucleus tractus solitarii), and was removed from an area just dorsolateral to the central canal. The A5 region contains catecholaminergic cell bodies, most of which lie between the superior olive and the facial nerve, close to the ventral surface of the brain. The A6 region (locus coeruleus), was removed from the tegmentum medial to the superior cerebellar peduncle. The A7–A8 cell bodies (part of the nucleus cuneiformis) are found at the level of the border of the mesencephalon and pons, dorsal to the medial lemniscus and medial to the lateral lemniscus.

Cortical, limbic and hypothalamic regions were removed with a microdissecting knife. Samples from the septum, pre-optic area and caudate-putamen were removed from sections at the anterior commissure level, where the septum is delimited by the lateral ventricles, the corpus callosum and the anterior commissure. The preoptic region lies between the anterior commissure and the ventral surface of the brain medial to imaginary vertical lines drawn through the lateral ventricles.

Samples of tissue from the medial basal hypothalamus (including median eminence, arcuate nucleus and a part of the ventromedial nuclei) were dissected from sections at the median eminence level. The amygdala was removed from the same section, and was limited by the optic tract medially, the caudate-putamen dorsally and the external capsule-piriform cortex laterally. Samples were dissected from the cortex and hippocampus.

The hypothalamic nuclei, the olfactory tubercle and the nucleus interstitialis striae terminalis, were removed, and both the compact and reticular zones of the substantia nigra were dissected between the lemniscus medialis and the crux cerebris.

PNMT in brain samples was measured by a modification of the method previously described² as follows. Brain tissue from one rat was homogenised in 65 μ l of 0.2 M Tris-HCl buffer, pH 8.6, and 5 μ l was removed for protein determination¹¹. After centrifugation, 50 μ l of the supernatant was transferred to 13-ml glass-stoppered centrifuge tubes. The reaction was initiated by addition of 100 μ l of a solution containing 4.5 μ mol of phenylethanolamine and 0.54 nmol of ³H-methyl-S-adenosyl-1-methionine (New England Nuclear Corp., specific activity 4.5 mCi μ mol⁻¹). Blanks were prepared by omitting the substrate from the incubation mixture. The tubes were incubated for 30 min at 37° C. The reaction was stopped by the addition of 0.5 M borate buffer, pH 10, and the radioactive product was separated from the ³H-methyl-S-adenosyl-1-methionine by extraction into toluene

TABLE 1 PNMT activity in rat brain nuclei

Region	PNMT
A1 (C1)	41.5 \pm 5
A2 (C2)	40.3 \pm 4.3
A5	5.6 \pm 1.4
A6 (locus coeruleus)	12.0 \pm 1.2
A7-A8	6.1 \pm 1.1
Cerebellar cortex	Not detectable
Frontal cortex	Not detectable
Cingulate cortex	Not detectable
Piriform cortex	Not detectable
Hippocampus	Not detectable
Amygdala	Not detectable
Septum	6.3 \pm 1.7
Nucleus interstitialis striae terminalis	6.7 \pm 0.8
Olfactory tubercle	Not detectable
Preoptic region	7.7 \pm 0.7
Hypothalamus	
Basal hypothalamus	15.9 \pm 2.2
Nucleus periventricularis	8.0 \pm 0.9
Medial forebrain bundle (anterior)	6.2 \pm 0.5
Nucleus dorsomedialis	10.9 \pm 3.2
Nucleus suprachiasmatis	5.6 \pm 0.7
Nucleus supraopticus	5.2 \pm 1.3
Nucleus anterior	5.9 \pm 1.3
Nucleus paraventricularis	15.0 \pm 2.5
Area retrochiasmatica	9.7 \pm 3.4
Median eminence	15.6 \pm 3.0
Nucleus arcuatus	10.3 \pm 2.0
Nucleus ventromedialis	8.3 \pm 1.6
Nucleus perifornicalis	8.1 \pm 1.6
Nucleus premammillaris dorsalis	4.1 \pm 0.5
Nucleus premammillaris ventralis	4.9 \pm 1.4
Nucleus posterior hypothalami	5.1 \pm 1.0
Medial forebrain bundle (posterior hypothalamic level)	5.3 \pm 1.2

Brain samples were dissected and processed as described in the text. Results represent mean \pm s.e.m. for groups of eight animals. One unit of enzyme activity is equal to 1 pmol of ³H-N-methyl phenylethanolamine formed per mg of protein and per hour of incubation.

containing 3% of isoamyl alcohol (v/v). A 5 ml sample of the organic solvent was evaporated to dryness under a stream of air, and the radioactivity remaining was counted. The whole procedure was repeated using internal standards consisting of 1 U of purified PNMT¹³, and the results were corrected accordingly. The use of a methyl donor of high specific activity and a drying procedure to eliminate a volatile radioactive contaminant increased the sensitivity of the assay fifty-fold over that previously in use¹³.

No enzymatic activity was found when phenylethanolamine was replaced by β -phenylethylamine or tryptamine as substrates for the reaction. This finding suggests that the enzyme studied is PNMT, rather than the non-specific N-methyl transferase described earlier¹².

Our results indicate that PNMT activity is unevenly distributed in the rat brain, and is localised in specific areas. The greatest PNMT activity was measured in two areas, A1 and A2, which are rich in catecholamine-containing cell bodies⁹. Other areas containing many catecholaminergic neurones, such as A5 and A7-A8, were low in PNMT activity, and the region of the locus coeruleus (A6) showed intermediate values (Table 1). These results indicate that PNMT is not distributed homogeneously among regions rich in catecholamine-containing neurones.

PNMT activity could not be detected in any of the cortical areas examined, in the caudate, the amygdala or the olfactory tubercle (Table 1). The substantia nigra, the nucleus interstitialis striae terminalis and the septum showed relatively low levels of activity.

Enzymatic activity was detected in all of the hypothalamic nuclei studied as well as in the preoptic region. The PNMT activity was found to be lower than the dopamine- β -hydroxy-

lase and tyrosine hydroxylase activities found in similar hypothalamic nuclei.

PNMT was found to be unevenly distributed within hypothalamic nuclei. The largest concentrations were in the medial basal hypothalamus in the arcuate and paraventricular nuclei and in the median eminence. Intermediate concentrations were found in the paraventricular, dorsomedial, ventromedial and perifornical nuclei and in the area retrochiasmatica. Small concentrations were found in the rest of the hypothalamic nuclei.

Adrenaline and PNMT are present in high concentrations only in the adrenal medulla^{1,2}. PNMT and its product seem also to be present in nerves, however. Work with amphibians has provided evidence that PNMT is synthesised and transported in the axons of peripheral nerves¹⁴. Small quantities of PNMT²⁻⁵ and adrenaline^{6,7} have been measured in the brain of mammals. Hökfelt *et al.*¹⁰ reported an immunohistological technique for the visualisation of PNMT in the brain. The localisation of the enzyme that we report agrees well with the histological data.

The medial basal hypothalamus, a region rich in the catecholamines dopamine and noradrenaline (M.P. *et al.*, submitted for publication), plays an important role in neuroendocrine regulation. The fact that PNMT is concentrated in this region suggests that adrenaline can also be produced there. Thus adrenaline may have a role in the hypothalamic control of the anterior pituitary.

Learning impairment in rats after 6-hydroxydopamine-induced depletion of brain catecholamines

STEIN¹ suggested, on the basis of the effects of amphetamine and other adrenergic drugs on self-stimulation behaviour, that the reinforcement feedback of the consequence of an action was mediated by a noradrenergic pathway in the region of the medial forebrain bundle. Noradrenergic and dopaminergic pathways in this region of the brain have been mapped by Ungerstedt², and Crow^{3,4} has suggested that the gustatory and olfactory input to these pathways might fit them for a role in transmitting environmental feedback. Other evidence implicates the dopaminergic nigro-striatal pathway in memory function as well. Microstimulation in the pars compacta of the substantia nigra has been found to produce a memory impairment not found on stimulation of the surrounding nuclei⁵, lesions in the substantia nigra impair learning^{6,7} and pharmacological manipulation of the level of dopamine in the substantia nigra can impair learning and performance of rats in a delayed response task⁸. Crow⁹ has found that locus coeruleus lesions may completely abolish learning in a runway situation. This indicates the involvement of monoaminergic-containing neurones in memory function. 6-Hydroxydopamine produces a depletion of brain noradrenaline and dopamine when injected into the lateral ventricle of the rat brain¹⁰, and also a reduction in the activity of the biosynthetic enzyme tyrosine hydroxylase¹¹ consistent with the morphological finding of acute degeneration of the nerve terminals^{12,13}. Depletion of the monoaminergic neurones using 6-hydroxydopamine would therefore be predicted to impair learning behaviour, and has indeed been found to produce a transitory decrease in responding on a fixed-ratio schedule for water reward¹⁴. This, however, returned to normal within a few days. Conversely, an increase in responding on a variable interval schedule after 6-hydroxydopamine has been found¹⁵.

This latter effect, however, was shown to be on the emission of responses after training to a stable level and not on the learning process itself. Our results using a demanding motor-learning task, show severe impairment after 6-hydroxydopamine during acquisition itself, which is not due to gross motor paralysis or hypokinesia.

Twenty experimentally naive male albino Wistar rats, weighing about 200 g at the time of operation, were anaesthetised with ether and two doses of 6-hydroxydopamine, (150 µg dissolved in 15 µl of 0.9% saline with 1 mg ml⁻¹ ascorbic acid antioxidant) were injected, one each side, into the lateral ventricle 2 mm lateral and 1–2 mm posterior to the bregma in ten animals. Controls received injections of the vehicle solution. Both groups were pretreated with the monoamine oxidase inhibitor tranylepromine (5 mg kg⁻¹) 30 min before the operation to enhance the depletion of dopamine¹⁶.

Two treated animals died during the course of the experiment. Pretraining was begun approximately 10 weeks after treatment, acquisition started 2 weeks later and transfer 4 weeks after this. The animals were trained on a complex task in which they had either to pull or to push a ball out of a perspex tunnel to reach food¹⁷. The apparatus comprised two open-topped boxes 25 cm high, and base 22 cm × 25 cm, connected at floor level by a 23 cm long cylindrical plexiglass alley of inside diameter 10 cm. The boxes were identical except that one, the goal box, contained a food dish into which sugar pellets could be delivered by a Gerbrands feeder. The alley could be partially obstructed by a plastic ball, 8 cm in diameter and weighing 45 g, placed equidistant from the start and goal boxes. Attached to the ball by a rubber suction cup was a 3.8 cm handle made from a 4 BA screw. Movement of the ball in either direction could be blocked by metal pegs mounted on pivots over the top of the alley and protruding down from the roof through a longitudinal slit in the plexiglass. Both pegs were always left hanging down, although only one was locked so that the rat had no obvious clue as to which of the two responses was possible on any trial. The apparatus was weakly illuminated and the rat was observed by mirrors placed at 45° above the apparatus. The subjects were placed on a 2 h d⁻¹ food access schedule until their weights were approximately 85% of free feeding weight. Subsequently they were fed 15 g d⁻¹ of laboratory chow, immediately after the subject's last trial of the day. On day 1 of pretraining, the subjects were placed in the start box and given 5 min exposure to the apparatus with the ball removed, pegs hanging down and food cup overflowing with sugar pellets. Fifteen further trials were given in which now only 2 pellets were available in the food cup per trial. A further 34 trials were given in which the pellets were delivered by the Gerbrands feeder, one on entry to the goal box and another 4 s later. Acquisition testing was now started with the ball placed in the tunnel and the distal peg locked so that the ball could only be pulled out of the tunnel. The subject was given a 5 min trial to solve the problem and then removed from the apparatus if the ball was still in place. If the ball had been moved part of the way out by the end of 5 min a further 5 min was allowed, but the subject unconditionally removed at the end of this time. The amount of time spent actually in contact with the ball was noted, this being taken as a measure of how much the rat was trying to move the ball ('trying time') and hence being a better measure than 'total-time-in-the-apparatus-to-solution' which is made up of behaviour other than that oriented towards the ball. The movements of head and paws used in manipulating the ball were also noted. Forty-seven trials were given in all, and the cumulative 'total-time-spent-in-the-apparatus-before-solution' of the task noted for each animal. By trial 28, one treated and two controls had failed to solve the task and showed no sign of doing so. 'Shaping trials' in which the ball was placed half in and half out of the tunnel and then moved further back were given. These animals were classified as

TABLE 1 Performance on ball-in-tunnel task.

	Acquisition		Transfer one		Transfer two	
	Time to solution (min)	Trying time (s)	Time to solution (min)	Trying time (s)	Time to solution (min)	Trying time (s)
6-hydroxydopamine (n = 8)	65.8 ± 14.7	572 ± 126	45 ± 15	29 ± 12	6.8 ± 2.4	4.3 ± 0.9
Controls (n = 8)	8.75 ± 1.9 P, 0.05	80 ± 14 P, 0.001	87 ± 26 Not significant	49 ± 18 Not significant	7.0 ± 0.5 Not significant	4.9 ± 0.5 Not significant

Performance of controls and 6-hydroxydopamine treated animals on acquisition, transfer 1 and transfer 2 of the ball-in-tunnel task. 'Time to solution' is the total time spent in the apparatus before solving the task; 'trying time' is the time spent in contact with the ball manipulating it. Values given are means and standard deviations for each group.

FIG. 1 Trying time (a) and time in apparatus (b) for the control and treated animals plotted against their position in the overall rank order of times for both groups. The animals separate out into two distinct groups, that is rapid solution controls and slow solution treated, with very little overlap. Of the 16 subjects used, two controls and one treated failed to solve acquisition within 28 trials and were dropped from the analysis of acquisition times. □, Controls; ■, treated.

failures and dropped from the analysis of acquisition. At the end of 47 acquisition trials, the proximal peg was locked and the other released and transfer testing begun with the animals being transferred from pull to push during the course of 28 trials. A second transfer phase was then started in which the animals were transferred back to pull. The total time in the apparatus for successful transfer was noted in each case. (Table 1).

On both 'trying time' and 'total-time-in-apparatus-to-solution' the 6-hydroxydopamine animals were severely impaired relative to the controls. (Fig. 1). On both transfer 1 and transfer 2, there was no significant difference between the groups, all animals mastering the second transfer within one 5 min trial. At the end of transfer 2 the animals were killed by decapitation and the brains rapidly removed, chilled and dissected into regions according to the method of Glowinski and Iversen¹⁸. The striatum, hypothalamus and cortex were homogenised in distilled water (1:10(w/v)) and 10 µl aliquots taken for radiochemical assay of tyrosine hydroxylase^{19,20}, the results of which confirmed that the 6-hydroxydopamine animals had sustained severe losses of adrenergic neurones in the hypothalamus, cerebral cortex and corpus striatum (Table 2).

The severe impairment in acquisition in the treated animals cannot be attributed to a motor impairment. The general mobility and time spent in the tunnel was the same in both groups. Each treated animal showed the normal range of head and paw movements and the frequency of these movements was the same in both groups. It also seems unlikely that the deficit is motivational as the treated animals spent as much time as controls in behaviour orientated towards the ball (measured as cumulative time in physical contact with the ball for each trial). Although this measure decreased after the first few trials as the animals habituated to the ball, it decreased equally for both groups, from an initial value that was virtually identical for both treated and control groups.

TABLE 2 Tyrosine hydroxylase activity (DOPA formed pmole h⁻¹ g⁻¹ wet weight).

	Striatum	Hypothalamus	Cortex
6-Hydroxydopamine (n = 8)	35.6 ± 12.0 (8.1%)	19.4 ± 4.5 (16.4%)	2.48 ± 2.32 (14.9%)
CONTROLS (n = 8)	438 ± 25.5	118 ± 8.7	16.7 ± 2.4

Mean and standard error of the tyrosine hydroxylase activity of the three brain areas (see text). These values in the 6-hydroxydopamine-treated animals are also expressed as % control value for that region.

Nor do the treated animals suffer from a retention defect, as once they had mastered the task they, without exception, performed perfectly on every subsequent trial and did not show the pattern of occasional failures expected with a retention defect. Thus 6-hydroxydopamine treatment produced a severe impairment in the actual learning process itself, as distinct from retention or emission of responses. Two related questions remain for future research. First, is the deficit specific to learning the complex motor sequences required for this demanding task, or general to all learning dependent on reinforcement? Second, dopaminergic systems are implicated in complex motor functions and noradrenergic systems with reinforcement mechanisms. The intraventricular 6-hydroxydopamine treatment severely depletes both dopamine and noradrenaline from the forebrain and selective lesion techniques using 6-hydroxydopamine will be employed to determine whether one amine rather than the other underlies the learning deficit.

We thank Dr L. L. Iversen for his help in performing the tyrosine hydroxylase assays, C. D. Andrews for performing the 6-hydroxydopamine injections, and Dr M. J. Morgan for allowing the use of his apparatus.

Activation of human T and B lymphocytes by polyclonal mitogens

LYMPHOCYTES can be activated *in vitro* by a variety of so-called polyclonal stimulants or mitogens (reviewed in refs 1, 2 and 3). These responses characteristically involve a larger proportion of cells than observed with antigen as the eliciting ligand, and the initiating events are widely believed to be independent of any immunogenicity possessed by the stimulant. These features of polyclonal responses provide the rationale for the use of such systems both as a model for the study of activation processes in lymphocytes²

* Cell surface markers for human T and B lymphocytes reviewed in refs 17 and 18. Detailed methods for these markers are published elsewhere^{19,20,30}. Values given represent mean ± standard error of five to twenty-seven determinations. Mean value only given where number of observations (in parentheses) was less than five—means not tested.

† Rabbit anti-human brain serum absorbed with chronic lymphocytic leukaemia (CLL) cells.

‡ Rabbit anti-CLL cell serum absorbed with thymocytes³⁰.

§ Spontaneous rosette formation at room temperature with sheep erythrocytes (<2-week-old).

|| Rabbit anti-human immunoglobulin (polyspecific).

†† Rosette-forming cells with receptor for C3. Sheep red cells + rat IgM anti-sheep red cell antibody + mouse serum (complement). Test performed on a rotatory shaker at 37°C.

** Tonsils were obtained from patients undergoing tonsillectomy for recurrent throat infections. Spleens used in these experiments were obtained from accident cases. Single cell suspensions prepared using an Ultra-Turrax homogeniser followed by filtration directly through glass wool at room temperature to remove aggregates of cells.

††† T cells purified by filtration of T and B cells through columns of nylon fibres (Fenwall Leukopak)^{19,21,32}. Optimal conditions are described elsewhere¹⁹. Yields of T cells were 49 ± 2.9 (s.e.)%. T cell suspensions contained less than 1% cells capable of phagocytosing polystyrene particles in 50% foetal calf serum at 37°C.

‡‡ B cells were purified by removing those (T) cells forming spontaneous (E) rosettes by density centrifugation in Ficoll-isopaque¹⁹. Re-rosetting and a second separation (double cycle) was necessary to reduce T cell contamination to less than 0.1%. B cell yields were 62–83%. The proportions of phagocytic cells was not routinely assessed in these populations but is likely to be somewhat enriched at least with respect to monocytes, compared with the initial cell suspensions. Tonsil cell suspension contained 0.5% to 2% phagocytic cells and spleen cells 8% on the single occasion that they were assayed. Blood monocytes purified by the method of Huber and Fudenberg³³ were unreactive with all antisera used and did not form spontaneous rosettes. In a single experiment they did not form rosettes with EAC (mouse).

and clinically for the assessment of proliferative potential of blood-borne lymphocytes⁴.

Both of these aims have been facilitated by the finding that T and B lymphocytes in mice respond selectively to all mitogens so far tested with the exception of pokeweed mitogen (PWM), which stimulates both T and B cells^{5,6} and may in fact contain separate T and B mitogens. (F. Loo, personal communication). This selectivity is most clearly observed with lectins (such as phytohaemagglutinin (PHA) and concanavalin A (conA) and bacterial lipopolysaccharides which activate T and B cells respectively^{1–3}. Most polyclonal mitogens do however seem to bind equally well to both 'responder' and 'non-responder' cell types^{7–9}, and under appropriate circumstances (for example, insolubilisation of lectins^{10–11}) responses can be induced in a normally unresponsive population.

These convenient relationships are challenged by recent observations; the first, that some mouse^{1,12} and human¹³ B lymphocytes do respond to T mitogens in the presence of activated T cells, and second that human tonsillar B lymphocytes purified by a digestible immunoabsorbent method respond directly to PHA^{13,14}. The latter observation contradicts earlier circumstantial but nevertheless compelling evidence from studies on patients with selective immune-deficiency diseases which suggested that PHA was selective for T cells in man¹⁵. Indeed on the basis of these results and other data from mice, rats and chickens¹⁶ the proliferative response to PHA has been widely used to assess T cell status in man⁴.

We have investigated this problem by the application of a series of cell surface markers^{17,18} which readily distinguish T and B cells in man (Table 1). The T or B cell origin of activated lymphoblasts has been assessed in cultures containing T plus B cells, B cells only or T cells only. Purification of T and B lymphocytes was carried out by negative selection: T cells were eliminated by density sedimentation of cells which had formed 'spontaneous' rosettes with sheep erythrocytes and B cells removed by adherence to nylon fibres¹⁹. Lymphocytes from tonsils, spleen and blood have been extensively studied with different culture conditions, media and mitogen concentrations.

Figure 1 illustrates representative results using optimal doses of PHA and PWM to stimulate tonsil and spleen lymphocytes. Tonsillar T cells responded well to both PHA and PWM. B lymphocytes were not activated by PHA and gave only a small response with PWM. In cultures containing both T and B cells, T lymphoblasts predominated in the response to both PHA and PWM. But up to 15% of the PHA-activated lymphoblasts in tonsil cells cultures with either Dulbecco's or RPMI medium on day 3 may be B cells. Repeat experiments on tonsils and also with blood lymphocytes have given consistent results. The response profile of spleen cells in RPMI medium was different from that of tonsils. T lymphoblasts again predominated the PHA response of unseparated cells (85%); however the majority (88%) of lymphoblasts in PWM stimulated cultures were B cells. Purified B lymphocytes responded well to PWM but as with tonsil B cells no activation was detectable with PHA. Weak but significant spleen B lymphocyte responses have also been induced by *Escherichia coli* lipopolysaccharide (LPS) and staphylococcal enterotoxin B. (unpublished observations of G. J. and M. F. G.).

These results with human lymphocytes parallel our earlier observations of the cell types responding to PHA and PWM in mice², but they contradict those of Phillips *et al.*^{13,14}. While it can be agreed that the response to PHA of mixed T plus B lymphocyte cultures may involve a small and perhaps variable B cell component we could not confirm the results suggesting that purified B cells respond to PHA independently of T cells. The failure of purified human B lymphocytes to respond to PHA has also recently been found when cell purification was achieved by using cytotoxic anti-T lymphocyte sera (refs 20 and 21, and M. Cooper, personal communication). In addition there is a considerable body of clinical data which illustrates clearly that lymphocytes from patients with thymic aplasia which are almost entirely B cells do not respond to PHA^{22,23}. Responsiveness can however be instated by T cell reconstitution following thymus grafting²².

Despite this compelling weight of evidence the positive result of Phillips and Roitt cannot be ignored and demands an explanation. If we assume that the discrepancies do not

FIG. 1 Response of human T and B lymphocytes to phytohaemagglutinin and pokeweed mitogen *in vitro*. □, Lymphoblasts positive for T cell surface markers. ■, Lymphoblasts positive for B cell surface markers. a, Tonsil; b, spleen. The culture methodology was essentially as described previously^{18,28}. Here tonsil cells were cultured in Dulbecco's Modified Eagle's Medium with 10% heat-inactivated human AB serum, and spleen cells in RPMI 1640 with 10% heat inactivated foetal calf serum. PHA was the purified preparation from Burroughs Wellcome and the responses shown are with $2 \mu\text{g ml}^{-1}$ assayed on day 3. PWM has protein derivative of *Phytolacca americana* prepared by TCA precipitation of a crude saline homogenate of stems and roots. The responses shown are with $10 \mu\text{g ml}^{-1}$ on day 3. The proportions of T and B cells in the cultures at 0 h were within the range indicated in Table 1. T lymphoblasts were typed as (S-RFC⁺, Ig⁺, B-Ag⁺) and B lymphoblasts as (S-RFC⁺, Ig⁺, B-Ag⁺), see Table 1. In additional experiments presumptive T and B lymphoblasts were also typed with EAC, anti-T cell serum and an anti-T lymphoblast serum analogous to that described by Phillips and Thomas¹⁴. Results with these markers paralleled very precisely those with the three markers used routinely. Aggregates of lymphoblasts were disrupted by vigorous pipetting and in occasional experiments with an Ultra-Turrax homogeniser. Rosetted suspensions were stained with 0.1% toluidene blue and viewed under ordinary light. Binding of anti-T, anti-B and anti-Ig sera to lymphoblasts in suspension was assayed using fluorescein-labelled goat anti-rabbit immunoglobulin and viewed with a Vickers M41 Photoplan fluorescence microscope with incident illumination. In all assays only cells with diameters greater than $10 \mu\text{m}$ were scored as lymphoblasts. Analysis of May-Grunwald/Giemsa stained smears confirmed that over 95% of enlarged cells were indeed lymphoblasts. Absolute numbers of lymphoblasts were counted and the response expressed as the number of lymphoblasts in relation to the initial cell number in the culture.

relate to quantitative problems or mistaken cellular identity then the following possibilities seem to us as the only plausible explanations for the discrepancy: our methodology may be inadequate for B cell responses to PHA either because culture conditions themselves are suboptimal and biased towards T cells, or alternatively because we have either lost or suppressed potentially responsive B cells during our purification procedure. We suspect this explanation is

unlikely to be correct since our B cell cultures do respond to PWM by both morphological transformation and DNA synthesis (30% of PWM-stimulated B lymphoblasts incorporate thymidine between days 3 and 4; unpublished observations of G. J. and M. F. G.). Moreover our culture conditions and media do not differ in any obviously significant way from those of Phillips and colleagues (ref. 13 and personal communication from Roitt and Thomas). Clearly however it is not possible at present to entirely rule out this explanation.

Alternatively it may be that the B lymphocyte responses to PHA observed by Phillips *et al.* are dependent upon facilitation mechanisms absent in our and others' systems. Potential factors of significance include the presence of macrophages, small numbers of activated T cells and subliminal stimulation by anti-immunoglobulin antibodies that are released during B cell purification on dextranase digestible Sephadex immunoabsorbent. Evidence can be procured to support all three possibilities. Macrophages have been found to potentiate PHA responses of both T cells²⁴ and B cell enriched cultures (L. Epstein, W. Kreth and L. Herzenberg, personal communication) and our own results indicate that contamination of B cells with as few as 2% T cells facilitates a PHA response. But this T-cell dependent response is also expressed principally by the 'residual' T cell (unpublished observations). Nevertheless the additional finding that culture supernatants of conA-activated T cells facilitate a small B cell response to this mitogen²⁵ provides evidence for a T-cell dependent, B cell response. Facilitation of PHA activation by binding of anti-human immunoglobulin antibodies which by themselves may be non- or minimally mitogenic seems to be a tenable explanation since such synergistic effects have been observed between anti-immunoglobulin and antigen in mice²⁶ and different mitogens in man²⁷.

These latter three explanations have at least the virtue that they can be readily tested. Regardless of the eventual outcome of this issue two points emerge which are relevant to the clinical application of proliferative responses to PHA. Under defined conditions the PHA response can be T-cell dependent and expressed predominantly by T lymphocytes themselves. In our hands optimal T cell proliferation with minimal B cell involvement is observed when cells are cultured in Dulbecco's modified Eagle's medium with 10% human AB serum. The PHA response can therefore be used as a quantitative or semiquantitative assay for the proliferative response of blood-borne T cells. A small proportion (5–15%) of B cells may however become activated in T-B cell mixtures (that is, in most clinical situations) and the application of cell surface markers is required to delineate this B cell contribution.

This work was supported by the Imperial Cancer Research Fund and the Medical Research Council of Great Britain. We thank Mr G. Stathopoulos for counting E rosettes in the spleen preparations, Dr J. Sachs of the London Hospital for supplying spleens and colleagues at University College Hospital, London for tonsils (not their own).

Restriction of *in vitro* T cell-mediated cytotoxicity in lymphocytic choriomeningitis within a syngeneic or semiallogeneic system

RECENT experiments¹⁻³ indicate that cooperation between thymus derived lymphocytes (T cells) and antibody-forming cell precursors (B cells) is restricted by the H-2 gene complex. Helper activity *in vivo* operates only when T cells and B cells share at least one set of H-2 antigenic specificities. Evidence is presented here that the interaction of cytotoxic T cells with other somatic cells budding⁴⁻⁵ lymphocytic choriomeningitis (LCM) virus is similarly restricted.

Both the cytotoxic assay used and the characteristics of the cells involved have been described previously⁶⁻⁸. Briefly, monolayers of C3H mouse fibroblasts (L cells) are grown in plastic tissue culture trays, infected with a high multiplicity of the WE3 strain of LCM virus and the cells labelled with ⁵¹Cr and overlaid (40:1) with the spleen cell preparation to be tested. Supernatants are removed between 15 and 16 h later and % ⁵¹Cr release calculated⁷. Results are expressed as mean \pm s.e.m. for four replicates. Cytolysis of

TABLE 1 Cytotoxic activity of spleen cells from various strains of mice injected i.c. 7 d previously with 300 LD₅₀* of WE3 LCM virus for monolayers of LCM-infected or normal C3H (H-2^k) mouse L cells.

Experiment	Mouse strain	H-2 type	% ⁵¹ Cr release†	
			Infected	Normal

	C3H/HeJ	k	77.8 \pm 0.8	24.5 \pm 1.5

* Other mice were injected with 2×10^6 LD₅₀, but levels of specific release were invariably lower due to the high dose immune paralysis^{8,20} associated with viscerotropic (WE3) LCM virus.

† % ⁵¹Cr release by normal spleen cells on infected targets ranged from: (experiment 1) 17.1 \pm 0.3 to 20.0 \pm 0.7; (experiment 2) 20.0 \pm 1.4 to 25.3 \pm 0.7; (experiment 3) 27.2 \pm 2.0.

infected L cells by CBA/H immune spleen cells has been shown to be a property of specifically sensitised thymus-derived lymphocytes, which act in the absence of both macrophages and substances secreted into the medium at large⁶⁻⁸.

Various strains of mice were injected intracerebrally (i.c.) with 300 mouse LD₅₀ of WE3 LCM virus. Mice were sampled 7 d later when, in CBA/H mice, maximal cytotoxic activity is found in lymphoid tissue^{6,7}. Only spleen preparations⁹ from mice sharing at least one set of H-2 antigenic specificities with the target monolayer caused high levels (40% to 50%) of specific lysis (Table 1). Spleen cells from nude control (nu/+ or +/+) mice, derived locally from CBA and Balb/C stock (Dr J. B. Smith, personal communication), were less active and lymphocytes from histoincompatible mice caused minimal specific release (< 5%) of ⁵¹Cr.

Spleen preparations from mice immunised 10 and 13 d previously were also assayed, as Marker and Volkert⁹ have reported that maximal cytotoxicity of C3H lymphocytes for L cells infected with the Traub strain of LCM virus occurs at 11 d after inoculation. High levels of specific ⁵¹Cr release were again recognised only in the histocompatible system (Table 2) activity declining, as has been shown previously⁷, from a peak on day 7.

Demonstration of reciprocal exclusion of cytolysis was essential to establish that mice possessing other than H-2* antigenic specificities are capable of generating cytotoxic T cells. Comparisons were thus made using similar targets from allogeneic mouse strains. Peritoneal macrophages were obtained¹⁰ from normal Balb/C and CBA/H mice, cultured in plastic tissue culture trays and infected¹¹ with WE3 LCM virus. Specific lysis was restricted to the syngeneic system

TABLE 2 % ⁵¹Cr release* from infected C3H L cells overlaid with spleen cells from mice sampled at 7, 10 and 13 d after intravenous inoculation with 2,000 LD₅₀ of WE3 LCM virus.

Mouse strain	Days after inoculation		
	7	10	13
CBA/H	72.0 \pm 2.0	66.4 \pm 1.4	27.5 \pm 0.5
Balb/C	26.1 \pm 0.7	28.0 \pm 1.6	22.7 \pm 1.8
C57Bl	27.3 \pm 1.1	24.3 \pm 1.8	24.0 \pm 0.4

* Levels of ⁵¹Cr release due to overlaying normal L cells with immune spleen cells, infected L cells with control spleen cells or with medium alone ranged from 17.1 \pm 0.4 to 24.0 \pm 1.4. Other mice were injected with 2×10^6 LD₅₀, but levels of specific release were invariably lower.

TABLE 3 % ^{51}Cr release from normal and infected peritoneal macrophages by spleen cells from control mice and from mice injected i.c. with 300 LD₅₀ of WE3 LCM virus 7 d previously.

 ND, Not done.

(Table 3). Comparable levels of specific ^{51}Cr release from isologous infected macrophages were caused by Balb/C and CBA/H spleen cells (overlaid at 20:1) from mice infected at the same time with the same dose of LCM virus, whereas histoincompatible macrophages were not damaged. Lysis was completely abrogated by treatment with AKR anti- θ ascitic fluid and guinea pig complement, but not by normal AKR ascitic fluid and complement. Though levels of ^{51}Cr release from macrophages were more variable than for L cells, probably because of inconsistencies in target cell concentrations and the higher background of non-specific lysis, the effect was both highly significant and repeatable.

The ability of T cells to cause lysis across an allogeneic barrier, when lymphocytes are sensitised to antigens specified by the H-2 gene complex, is well established^{12,13}. This also applies to L cells (H-2^k), which are readily lysed by spleen cells from C57Bl (H-2^b) mice stimulated in mixed lymphocyte culture by CBA/H (H-2^k) but not by Balb/C (H-2^d) lymph node cells. Sufficiently close association for lysis to occur is possible if the T cells is sensitised to alloantigens present on the surface of the target. Interaction between immune lymphocytes and cells expressing antigens expressed by LCM virus is, however, apparently confined to a histocompatible system, perhaps because it is only in this situation that the necessary intimacy of contact is achieved.

This restriction may possibly be overcome by previous treatment of the target population with trypsin. Balb/C (H-2^d) immune spleen cells will lyse recently trypsinised L cells (H-2^k) infected with the E-350 strain of LCM virus, the effect being completely abrogated by treatment with a rabbit anti-mouse brain serum cytotoxic for T cells¹⁴. Our experiments with previously trypsinised WE3-infected L cells have, to date, given equivocal results because of the high background of non-specific ^{51}Cr release.

An alternative possibility that must be considered in LCM is that the process of virus maturation⁵⁻⁶ through the cell membrane causes changes in self components, which are recognised only within the syngeneic or semi-allogeneic system. There is ample evidence¹⁵⁻¹⁶, for instance, that concentrations of H-2 antigens in the cell membrane are decreased in cells productively infected with budding viruses. The cytotoxic T cell may thus be recognising altered self, the implication being that LCM is essentially on autoimmune phenomenon.

These results impose a possible constraint on attempts to demonstrate cytotoxic T cells in infections of man and domestic mammals, where histocompatible cell lines and inbred strains are not available. Perhaps isologous macrophages or lectin-transformed peripheral blood leukocytes may prove

suitable targets in at least some disease states. Restriction of cell-mediated cytotoxicity within a syngeneic or semiallogeneic system may prove a reliable index of T cell involvement in species where the θ marker is not available, lysis across this barrier indicating an antibody-associated process¹⁷⁻¹⁹.

Production of colony-stimulating activity by human lymphocytes

THE clonal growth of human bone marrow cells *in vitro* requires the presence of a stimulatory substance(s) designated colony-stimulating activity (CSA)^{1,2}. Data available from various clinical and animal experiments suggest that CSA is, or is related to, a physiological controller of granulopoiesis^{3,4}. Although the precise biological role of CSA is still uncertain, considerable insights into leukopoietic mechanisms have been gained from the study of interactions of CSA and haemopoietic cells *in vitro*. Two sources of CSA have been identified that stimulate colony formation from human bone marrow: certain foetal tissues and peripheral blood leucocytes^{3,4}. The observation that CSA is produced by white cells led naturally to hypotheses concerning the feedback control of stem cells by mature leukocytes^{3,5}.

Within the past year, three groups of investigators have fractionated human buffy coat into its component leukocyte subpopulations and identified the monocyte as the principal source of CSA⁵⁻⁷. Monocyte-derived macrophages and the human alveolar macrophage also elaborate CSA, whereas neutrophils and unstimulated lymphocytes do not⁸. Recently, however, we examined the effect of mitogens on human lymphocytes and observed that lymphocyte blast transformation was associated with the elaboration of CSA. Lymphocyte-derived CSA stimulated the production of bone marrow colonies containing both granulocytes and mononuclear phagocytes. These observations suggest that granulopoiesis is influenced by humoral substances released from lymphocytes reacting to appropriate stimuli.

Pure populations of neutrophils, monocytes and lymphocytes were separated from peripheral blood as previously described⁵: monocytes and PMN were separated by Ficoll-Hypaque gradients and glass adherence, lymphocytes by removal of other cells adherent to nylon fibre columns. As judged by morphology, peroxidase and alpha-naphthyl butyrase cytochemistry, and lack of phagocytosis, the lymphocyte populations were more than 98.5% pure. Contaminating monocytes were less than 0.1% of the populations—a number insufficient to account for the observed results. Rare nucleated erythrocytes and damaged neutrophils were observed as contaminants. Pure populations of monocytes, neutrophils or lymphocytes were cultured in Leighton tubes at 1.5×10^6 ml⁻¹ in McCoy's medium containing 2 or 15% foetal calf serum and either phytohaemagglutinin-P (PHA, Difco, 35 µg ml⁻¹), pokeweed mitogen (Grand Island Biological Co., 1:100 dilution), or saline. After 2-6 d the cell-free conditioned medium was collected and tested for CSA after incorporation of 0.05 or 0.1 ml into 0.5% agar underlayers. Normal human bone marrow was tested for its response to this conditioned medium by incorporating 2×10^6 cells in 0.3% overlayers^{1,5}. After incubation at 37° C for 8-10 d the colonies were counted, smeared and stained for morphological analysis.

As previously described^{5,8}, conditioned medium from monocyte preparations had CSA, whereas conditioned medium from unstimulated lymphocytes had no detectable activity. However, incubation of lymphocytes with PHA resulted in detectable stimulatory activity after 3-6 d. The results with pokeweed mitogen were variable until day 6, when low levels of CSA were consistently detected. Table 1 summarizes the results of one experiment which was repeated seven times.

PHA stimulated neither the production or release of CSA by neutrophils nor enhanced monocyte-related CSA. When lymphocytes were incubated in the absence of mitogen and the resultant conditioned medium was later combined with PHA or pokeweed mitogen, no detectable activity resulted. Neither PHA nor pokeweed mitogen—when incorporated directly in agar underlayers—had a detectable direct effect

TABLE 1 CSA activity of conditioned medium from cell cultures.

Cell type	Duration of culture (d)	Addition	Colonies per 2×10^6 marrow cells*
Neutrophils	2-6	Saline	0-2
Neutrophils	2-6	PHA	0-2
Monocytes	2	Saline	75 ± 7
	5	Saline	72 ± 6
	5	PHA	78 ± 8
Lymphocytes	2-6	Saline	0-2
	3	PHA	15 ± 3
	4	PHA	21 ± 3
	6	PHA	34 ± 5
	3	PWM	4 ± 3
	6	PWM	11 ± 3

PWM, pokeweed nitrogen.

* 0.05 ml of conditioned medium was incorporated in a 0.5 per cent agar underlayer, and 2×10^6 normal human bone marrow cells in a 0.3% agar overlayer.

on bone marrow growth. When lymphocytes were incorporated directly in agar with mitogen, many small cell clusters resulted in the underlayer, which obscured evaluation of growth of bone marrow colonies in the upper layer.

The time course of production of lymphocyte CSA in response to PHA is shown in Table 1. Activity was not detectable before day 2, but then increased progressively until day 6. It was detectable when cells were cultivated in 2% foetal calf serum, as well as in the more usual 15%. Both neutrophilic and mononuclear cell colonies developed in bone marrows stimulated by lymphocyte conditioned medium. Occasionally, predominantly eosinophilic colonies were observed (less than 15% of colonies).

Several lines of evidence support the concept that all mammalian haemopoietic cells ultimately arise from a common pluripotent stem cell pool^{4,9}. Relatively recent evidence indicates that this is true for lymphoid, as well as non-lymphoid cell lines¹⁰. The factors controlling differentiation into one or another cell line are poorly understood but almost certainly involve short-range microenvironmental factors as well as systemic hormonal mechanisms¹¹. Granulopoiesis and mononuclear phagocyte production *in vivo* are influenced by many stimuli, including bacterial products, antigens and leucocyte removal and administration^{8,12-14}.

The data reported here indicate that with mitogen-induced blast transformation, lymphocytes can elaborate a substance(s) able to stimulate the formation of granulocyte and mononuclear cell colonies from human bone marrow *in vitro*. These observations may explain the high levels of CSA observed in mice after antigenic stimulation¹⁴, and may serve to explain enhanced granulopoietic activity in certain types of humoral and cellular immune reactions. It is not yet known whether lymphocyte CSA is identical to that produced by mononuclear phagocytes. The observation of eosinophilic colonies arising under the stimulus of lymphocyte CSA may provide insights into the intriguing relationship between lymphocytes and the development of an eosinophilic response^{15,16}.

In vivo localisation of radiolabelled antibodies to carcinoembryonic antigen in human colon carcinoma grafted into nude mice

SEVERAL attempts have been made to show the specific localisation *in vivo* of anti-tumour antibodies. Most of these studies, however, either in experimental animals^{1,2} or in humans³ were performed with antibodies obtained by adsorption and elution from poorly characterised crude tumour fractions.

Here we report the specific localisation of ¹²⁵I-labelled antibodies against carcinoembryonic antigen (CEA) in heterografts of human colon carcinomas growing in nude mice and show that they can be detected by external scintillation scanning. This model system enables us to test the ability of antibodies directed against a well-characterised human tumour-associated antigen to concentrate in human tumours without performing preliminary experiments in patients.

We have recently shown⁴ that CEA as identified by Gold and Freedman⁵ was present in heterografts of human colon carcinomas serially transplanted into nude mice (Balb/c

Nu-Nu from G1. Bomholtgard Ltd., Ry, Denmark). CEA was demonstrated on cryostat tumour sections by indirect immunofluorescence using a highly specific rabbit anti-CEA antiserum⁶. The histology of the grafted tumour as well as the localisation of CEA in this tissue was identical to that observed in the primary tumour. Also, CEA extracted from tumour grafts by the perchloric acid method⁷ was found by radioimmunoassay^{8,9} to be immunologically identical to reference human CEA⁶ and, moreover, to be present in similar concentrations in both heterotransplanted and primary tumours. Using a double antibody radioimmunoassay^{10,11}, it was possible to detect circulating CEA levels of 20-70 ng ml⁻¹ in sera of nude mice bearing colon carcinoma tumours larger than 1 g. No CEA was detected in sera of nude mice bearing colon carcinomas smaller than 0.5 g or bearing other human tumours, including breast carcinomas, hypernephromas and melanomas.

Anti-CEA antibodies were isolated by adsorption-elution from a specific immuno-adsorbent prepared in the following way. Eight milligrammes of purified CEA⁶ were polymerised with 200 mg of BSA at pH 4.8, using 2 ml of 1% glutaraldehyde solution¹². Following homogenisation, the polymer was mixed with an equal volume of Sephadex G-25 and packed in a 1 cm diameter column. One ml of hyperimmune goat anti-CEA antiserum which exhibited little reactivity with the non-specific cross-reacting antigen (NCA)¹³⁻¹⁵, was run through the column at a flow rate of 3 ml h⁻¹. The adsorbed antibodies were eluted with 3 M KSCN¹⁶, dialysed against 0.01 M Tris-HCl buffer, pH 7.5, and concentrated to 1 ml. This antibody fraction contained 2 mg of protein and was able to bind 50% of 1 ng of CEA at a dilution of 1:70,000 when titrated in the radioimmunoassay.

A hundred microgrammes of the antibody fraction were labelled with 2 mCi of ¹²⁵I using the lactoperoxidase method¹⁷, mixed with 1 ml of normal goat serum and filtered on a Sephadex G-200 column. The 7S antibody fraction was collected and used immediately for the localisation experiments. About 60-70% of the radioactive material in the 7S fraction was specifically bound to the CEA immuno-adsorbent. For control experiments, normal goat 7S globulins, treated with 3 M KSCN, were labelled with ¹²⁵I and further purified on Sephadex G-200.

Volumes of 0.2 ml of the 7S fraction containing about 2 µg of radioactive antibody (specific activity: 8 µCi µg⁻¹) and

Fig. 1 *a*, Nude mouse bearing a heterograft of human colon carcinoma is shown in the scanning position. *b*, The total-body scan from the same mouse obtained 3 d after injection of 2 µg ¹²⁵I labelled anti-carcinoembryonic antibodies (dose of radioactivity injected = 16 µCi).

* Concentration of either antibody or normal 7S globulin (N 7S) expressed as % of the total specific radioactivity per g of tissue.

† Tumour: liver or tumour: muscle ratio are obtained by dividing the tumour concentration of either antibody or normal 7S globulin by the organ concentration of each of these proteins.

‡ Specificity indices are obtained by dividing the tumour: normal organ concentration ratio of antibody by that of normal 7S globulin.

200 µg of normal goat 7S globulins were injected intravenously into nude mice bearing subcutaneous grafts of human colon carcinomas. At different time intervals ranging from 2 h up to 3 d after injection, mice were scanned with a 3 inch crystal photoscanner (Picker Magnascanner 500). During the scanning procedure, the mice, anaesthetised by intraperitoneal injection of phenobarbital, were immobilised in the prone position as shown in Fig. 1a. After 2–6 h, the radioactivity was homogeneously distributed throughout the mice with no apparent localisation in the tumours. No difference could be detected between tumour-bearing mice and normal controls. After 1 d, however, the radioactivity began to localise in the tumour area and gave an optimal detectable contrast by day 3 (Fig. 1b). At that time, the mice were killed and scanned again after separating the tumour from the body. This last scanning confirmed that the major radioactive site was related to the tumour and not to the adjacent liver.

After complete dissection of the animal, each organ and pieces of the body were weighed and placed in well-type scintillation counter. For the 24 g mouse seen in Fig. 1, it was found that 40% of the total radioactivity recovered was concentrated within the 1.8 g tumour. Several other scanning pictures showing clear tumour localisation were obtained with different mice bearing variously sized heterografts, all derived from the same colon carcinoma (Co 115). The smallest tumour nodule detectable by scanning weighed 200 mg. Grafts of two other human colon carcinomas (Co 111 and Co 112), with more differentiated histology and less abundant stroma and vascularisation⁴ than Co 115, showed a lower specific concentration of antibodies (see Table 1) which were not detectable by scanning.

To take into account the possible non-specific accumulation of proteins in the extravascular space and necrotic regions of the tumour¹⁸, the antibody localisation was studied by simultaneous injection of ¹³¹I-labelled antibodies and ¹²⁵I-labelled normal goat 7S globulins (N 7S). In two experiments, the labels were reversed. The average values of four representative experiments performed in mice bearing Co 115 tumour are presented in Fig. 2. The results are expressed in percentage of the total radioactivity recovered per g of each tissue studied. The concentration of antibodies in the tumour was more than two-fold greater than N 7S whereas in normal tissues the antibodies had lower values than the control protein.

In Table 1 the individual results from seven different experiments are summarised. Concentration values of labelled antibodies and N 7S observed in tumour, liver and muscle

FIG. 2 Distribution of goat anti-CEA antibodies and normal goat 7S globulins in nude mice bearing heterografts of human colon carcinoma (Co 115). Three days after simultaneous injection of both proteins each labelled with a different iodine radioisotope (as described in the text), the tumour and different tissues were weighed and then measured in a dual channel well-type scintillation counter. Bar graphs represent the average value of four different experiments (% of total specific radioactivity recovered per g of tissue) for antibodies (shaded area) and for normal goat 7S globulin (open area). The solid lines represent the range of values.

can be compared. For both radioactive preparations, the ratio of tumour:normal organ concentration was calculated. A specificity index was obtained by dividing the concentration ratio of antibodies by that of N 7S. This index was significantly positive in all colon carcinomas tested, including Co 111 and Co 112 (experiments V and VI), which were not detectable by scanning. In contrast, when the same experiments was performed in C57Bl/6 mice bearing a transplanted EL4 solid lymphoma (experiment VII), the specificity indices were not significant.

Evidence was obtained that the specificity of antibody localisation was decreased with the presence of necrotic tissue within the tumour. In experiment II, the tumour exhibited a significant degree of central necrosis. Despite a high absolute concentration of antibodies in this tumour, relatively low specificity indices were observed compared with those obtained for less necrotic tumours (experiments I, III and IV). Furthermore, when the radioactivity of a small non-necrotic fragment selected from the tumour of experiment II was measured, the tumour:liver ratio of antibody was 14.0 and the specificity index reached 8.6 (the highest value yet observed). In three other experiments, cells from disrupted tumour fragments were counted after several washes with buffered saline. It was found that about 55% of the antibody radioactivity remained bound to the cells compared with 15% of the N 7S radioactivity.

It should not be concluded from these experimental studies that the injection of patients with labelled heteroanti-CEA antibodies will, in any case, enable the scanning detection of CEA-containing cancers. The major difficulties in humans would be the relatively large amounts of circulating CEA^{8,9,11}, as well as the presence of small quantities of CEA in non-malignant tissues^{6,19-21}. Further work is needed to assess whether the use of highly specific antibodies directed against CEA may open a new dimension in the field of tumour localisation by radioactive tracers.

We thank Professor H. Isliker for advice and suggestions, Dr B. Scazziga, Miss L. Cuendet and Miss R. Kollman, Thyroid Function Unit, Department of Medicine, University, of Lausanne, for assistance in radioactive scanning. Immunological detection of antigen(s) associated with rat colon carcinoma

CANCER of the colon and rectum is exceeded only by cancer of the lung as a cause of cancer death in the United States. Of the approximately 350,000 deaths from cancer in 1973, 47,400 were from cancer of the colon and rectum; of the approximately 665,000 cancers diagnosed in 1973, 79,000 were in the colon and rectum. Denmark, Great Britain, Ireland, Canada, New Zealand, Australia, Belgium and Austria have equally high or even slightly higher death rates from this disease and it is a significant cause of morbidity and mortality in most western countries. Improved surgical techniques and the development of new diagnostic methods have not significantly affected these mortality statistics¹.

A useful animal model for the study of human colon carcinoma is the rat bearing adenocarcinomas of the colon induced by 1,2-dimethylhydrazine (DMH)^{2,3}. Six to 8 months after initiation of treatment, 60 to 100 per cent of rats have one or more colon tumours which cause bleeding, intussusception or obstruction. The tumours are visible through the thin wall of the colon and are readily accessible for surgical or other treatment. Methods for early detection of tumours are needed for (a) development and evaluation of preventive or therapeutic measures and (b) studies of tumour development under dietary or other regimens designed to retard or enhance colon carcinogenesis³⁻⁵.

Human colon carcinomas produce a glycoprotein, carcinoembryonic antigen (CEA)⁶, which is detectable in serum⁷ or plasma⁸. Although CEA is not specific for colon tumours, detection and quantitation of circulating quantities may be useful in the diagnosis of colon and other cancers, for prognosis after surgical resection and for monitoring chemotherapy⁹. We have detected antigen(s) in DMH-induced rat colon carcinomas using antisera produced in rabbits (see below). Since the antigen(s) was found in the rat tumours but not in normal rat colon it may provide a rat model for CEA in human colon carcinoma.

Identification of the tumour-associated antigen analogous to human CEA, in the rat model described above would facilitate study of (1) the relationship between the blood level of antigen and size or other anatomic characteristics of colon tumours, (2) response of tumours to treatment, and (3) experimental induction and development of tumours.

Twenty-eight male, 4-week-old Sprague-Dawley rats (Charles River Laboratories) were fed a semisynthetic diet for 3 months, given ten weekly intragastric doses of DMH (30 mg kg⁻¹ in 0.9% NaCl) and killed when they developed signs of tumour in the intestine or ear duct. Then control rats were given 0.9% NaCl. At autopsy, colon tumours 3

mm or greater in diameter and sections of normal colon (starting 1 cm away from the tumour) were frozen in liquid nitrogen. A small section of tumour was fixed in 10% neutral buffered formalin and processed for histological examination.

Pooled tumours (4.2 g) were minced and homogenized for 1 h at 0° C in three volumes of 0.9% NaCl using a motor-driven Teflon pestle. The homogenate was centrifuged at 500 g and 4° C for 30 min; the supernatant was dialysed against distilled water for 60 h with fifteen 4-h changes. The non-dialysable portion was flash frozen in methanol-dry ice and lyophilized to dryness to yield 186 mg of product. Extracts were prepared, by the same procedure, from 4.9 g of normal colon from ten control rats and 5.3 g of normal colon from tumour-bearing rats. Portions of the three extracts were dissolved separately in 0.9% NaCl at a concentration of 4 mg ml⁻¹.

Antibodies to the tumour macromolecules were produced by giving New Zealand adult rabbits three weekly intramuscular injections of a mixture of 0.25 ml of tumour extract and 0.75 ml of aqueous aluminum hydroxide gel as an adjuvant¹⁰. The rabbits were bled 7 d after the last injection, injected with the tumour extract-aluminum hydroxide gel mixture and bled repeatedly for several weeks.

The blood was allowed to clot at room temperature for 1 h, held at 4° C overnight and centrifuged at 280 g and 4° C. Sera were decanted and centrifuged at 56° C for 30 min. Antibodies to tumour-associated antigens and normal rat tissue components were found in the antisera by double immunodiffusion (Ouchterlony) and counterimmunoelectrophoresis techniques on rehydratable Agarose media. Heterologous antibodies were removed from the antisera by absorbing with (a) extracts of normal rat colon (1 part to 100 parts of the antisera) and (b) affinity chromatography beads (CNBR-Sepharose, Pharmacia) to which normal rat colon macromolecules were coupled. Absorption was continued until the antisera did not react with normal colon components when assayed by the Ouchterlony technique. Two-fold serial dilutions of normal colon extracts were tested with the absorbed antisera to confirm that negative reactions were not due to formation of soluble immunocomplexes in the prozones of the antisera.

Absorbed antisera to rat colon tumours (10 µl) were reacted by the Ouchterlony technique with 10 µl of extracts of tumour, normal rat colon and normal colon from tumour-bearing rats for 48 h in a humid chamber at room temperature. Reaction was obtained only with extracts of tumour. Counterimmunoelectrophoresis was performed on prototype 35 mm Agarose strips (45 mA, 30 V, 60 min) in which macromolecules from the colon tumours and normal colon were electrophoretically transported to the absorbed tumour antibodies¹⁰. The same concentrations were used as in the Ouchterlony technique. This more sensitive technique supported the Ouchterlony results. When seven two-fold serial dilutions of colon tumour extract and of normal colon extract were reacted with a constant concentration of antibody to rat colon tumours, reactions were obtained with the tumour extract at all dilutions, but no reactions were obtained with dilutions of the normal colon extracts.

Preliminary work indicated that the absorbed antisera reacted with rat foetal extracts. Forty foetuses taken from four Sprague-Dawley rats on the fourteenth day of gestation were dissected free of maternal tissues, decapitated and their tails docked. Pooled foetuses gave 2.8 g of tissue from which a crude saline extract was prepared by homogenization and centrifugation. Counterimmunoelectrophoresis performed as described above indicated a strong reaction between foetal extract components and the tumour antibodies. Preliminary results indicate that the tumour antibodies do not cross-react with human CEA and that rat tumour antigen does not react with anti-CEA antisera. The difference may be one of species specificity as was found with α -foetoprotein produced by human or rat hepatocarcinomas¹¹.

Involvement of amino and sulphydryl groups in olfactory transduction in silk moths

ROZENTAL and Norris¹ found evidence of a chemosensory mechanism of olfaction and gustation in the cockroach *Periplaneta americana* that involves the formation of disulphide bonds. I wish to report that olfactory transduction in silk moths does not seem to involve disulphide links, although sulphydryl and amino groups are important.

Experimental evidence on mechanisms of molecular interaction with chemoreceptors might aid the choice among different theories of taste and olfaction²⁻⁸, and the silk moths are useful models for such work because the antennae of the males contain cells specialised to capture chemical information from a particular molecular species⁹⁻¹⁵. I have perfused amputated male antennae of the silk moths *Antheraea pernyi* and *Bombyx mori* with solutions of chemical reagents selective for protein side chains. (Previous control perfusions were performed with the specific solvents for the reagents.) Olfactory responses were measured by the electroantennogram method^{9,14}. Unlike that of *B. mori*, the sex pheromone of *A. pernyi* is not yet available, and so I prepared an extract from the female glands¹².

2,3-Dimethylmaleic anhydride (DMA) and 2-methylmaleic anhydride (citraconic anhydride, CA) are specific blocking agents for amino groups of proteins¹⁶, but their action is reversible by decreased pH. Olfactory responses were inhibited with DMA, pH 7.5, at a threshold concentration of 2 mM. On re-perfusion with control Ringer solution, pH 4.8, there was substantial reversal of inhibition. Figure 1a shows the electroantennogram responses before, during and after the reversal of inhibition by 4.7 mM DMA. Similar reversible inhibition was obtained with CA. There was also inhibition with ≥ 0.9 mM 2,4,6-trinitrobenzenesulphonic acid¹⁷.

Behavioural and other studies have suggested that sulphhydryl groups are involved in taste and olfaction in various insects¹⁸⁻²⁰ and man²¹. To test for such involvement in *A. pernyi*, I perfused antennae with N-ethylmaleimide (NEM) at pH 7.5. Inhibitions graded according to concentration were found (Fig. 1b). *p*-Chloromercuribenzoate was inhibitory at a threshold of 0.2 mM; appreciable reversal was achieved by re-perfusion with 1.0 mM reduced glutathione. Mersalyl (salyrganic acid) and iodoacetic acid inhibited, with thresholds of approximately 1 mM and 0.1 mM respectively. I found similar, though less strong indications that amino and sulphhydryl groups are involved in the olfactory process of *B. mori*; the antennae are less robust in successive perfusions than the larger antennae of *A. pernyi*.

The exact site of action of an inhibitor on a whole antenna is unknown, and rather than the receptor macromolecule, ion-channels or an ion-pump mechanism, for example, might be

FIG. 1 Olfactory responses (amplitude of electroantennogram) of *A. pernyi* male antennae after perfusion with reagents for (a) amino and (b) sulphhydryl groups of proteins. Since the concentration of pheromone in the extract of pheromone gland (see text) is unknown, the concentration of the stimulus is expressed in arbitrary units. a: ●, Control; ▽, 4.7 mM DMA at pH 7.5; ×, reversal of inhibition by re-perfusion with control Ringer adjusted to pH 4.8. b, Perfusions with various concentrations of NEM: □, control, followed by 0.1 mM NEM; △, control, then 1.0 mM NEM; ○, control, then 10.0 mM NEM. Data represent mean values for three antennae; the experimental variability was approximately ± 0.1 mV.

impaired. The latter is less likely, for standing potentials²² that I measured tended to be maintained after perfusion with inhibitors. The unambiguous identification of both the inhibitor target site and the modified groups, however, requires isolation of the receptor and the inhibition products.

The relatively high concentration needed for inhibition could indicate non-selectivity of action for the amino and sulphhydryl group reagents. Since diminished olfactory responses in *A. pernyi* did not change appreciably for almost 1 h after perfusion with the inhibitors, equilibrium may have been reached. But if the resistance to diffusive flux were high, because of a hidden site of action for example, the variation of concentration gradient with time would not be appreciable, thus giving rise to quasi-stationary diffusion²³. If so, the concentration of inhibitor at the binding-sites would be somewhat lower than in the perfusing system.

The next question I considered was whether disulphide groups might be involved in silk moth chemosensory transduction as they seem to be in the function of vertebrate acetylcholine receptors²⁴⁻²⁷ and taste and olfaction in *P. americana*¹. Antennae of *A. pernyi* were perfused with reduced glutathione, L-cysteine, dithioerythritol (DTE)²⁸ and β -mercaptoethanol. Inhibition was found only at concentrations greater than approximately 10 mM, and it was not reversible, suggesting non-specificity of action. Below 1 mM there was no detectable effect; from 1 mM to 10 mM responses were slightly activated; with DTE there was some activation even at 30 mM. A possible explanation for this activation is that receptor sulphhydryl groups were protected by the reducing agents. Similar results were obtained with *B. mori*.

A tentative conclusion is that, in contrast to findings with *P. americana*, interconversion between -SH and S-S^{1,29} is not characteristic of olfactory transduction in *A. pernyi* and *B. mori*.

I thank the Deutsche Forschungsgemeinschaft for financial support, Miss Carola Hahn for technical help and Drs D. Schneider and H. Dannenberg for facilities.

The α 1-acute phase protein response in rats as a possible indicator of the relative smoking risks of different cigarettes

AN increase in the serum levels of the α 1-acute phase protein, indicative of local tissue damage¹ has been shown in rats exposed to cigarette smoke for periods of up to 30 d. The increases correlated well with the degree of damage to the respiratory system as evidenced by the pathological changes observed *post mortem* in the lungs (L.A.E., T.E.B., D. A. Darcy and J. P. O'Sullivan, unpublished).

The greatest increases were in the rats exposed to the smoke of cigarettes made of flue-cured tobacco, which are by far the most popular type of cigarettes smoked in Britain. Considerable increases in the α 1-protein were also seen in rats exposed to the smoke of cigarettes made mainly from air-cured, unfermented tobacco, a type popular in France, Spain and other European countries. Rats exposed to the smoke of cigarettes made of air-cured fermented cigar tobacco, however, showed only a slight increase in their serum α 1-acute

FIG. 1 The effect of smoking 35 cigarettes on rat serum α 1-protein.

α 1-Acute phase protein determinations were carried out by the method of Darcy^{2,3} on 0.2 ml blood taken from a tail vein. Groups of five rats were then exposed to the smoke from 30 to 40 cigarettes in a Martin Wright smoking machine⁴. The machine was set to give a 35 ml puff of 2 s duration and the smoking period lasted 3 to 4 h. The animals were again bled for α 1-acute phase determination at a fixed time, usually 24 h after the end of their smoking period. Male rats, of the Wilkie hooded strain, aged between 10 and 20 weeks bred under minimal disease conditions were used. Control animals were sham smoked.

Figure 1 shows the time response curve to the smoke of 35 commercial English cigarettes (made of flue-cured Virginia tobacco). The optimum response appears to be

TABLE 1 Effect of different tobacco smokes on serum α 1-acute phase protein in rats.

Tobacco type	Country	Sugar content (%)	pH of smoke	Tar T.P.M. (mg)	Nicotine (mg)	No. of cigarettes smoked	Increase in α 1-acute phase protein units (\pm s.e.)*
Flue-cured cigarette	England	17.8	4.0	21.8	2.2	40	1.10 \pm 0.06†

phase protein. This could be of significance in relation to the relatively low lung cancer mortality of cigar smokers compared to cigarette smokers. As the acute phase proteins usually appear in increased concentration in the blood within a few hours of inflammation or tissue injury, it seemed possible that the α 1-acute phase protein response in the rat could offer a convenient rapid method of comparing deleterious effects and possible smoking risks of different cigarettes. We report here preliminary observations.

between 24 and 48 h, and a 24-h interval between the end of the smoking period and determination of the α 1-acute phase protein response was selected for comparison of the effect of the smokers of different tobaccos shown in the table.

Although only limited inferences should be drawn from these preliminary results, the smoke of cigarettes made from flue-cured, high sugar content tobacco seems to produce the greatest increases in α 1-acute phase protein. Increases to between five and seven times the control (presmoking) levels

were observed. The smoke of air-cured tobacco cigarettes and of cigarettes made from unfermented cigar tobacco produced increases of up to 3.5 times the control value. The lowest increases, to less than twice the control values were found in animals exposed to the smoke of cigarettes made from air-cured fermented cigar tobacco. This agrees with the findings of our longer-term experiments, and is consistent with the much lower risk of lung cancer in cigar smokers compared with cigarette smokers.

The effect on the serum α 1-acute phase protein does not seem to bear any direct relation to the tar and nicotine content of the smoke. There may be a possibility that the acid nature (pH 4) of the smoke of the high sugar content, flue-cured tobacco⁵ makes some contribution to the intensity of the α 1-protein response.

Synthetic insecticide with a new order of activity

We describe a new insecticide, related to the pyrethrins, and considerably more active than any other available compound, of whatever class (LD_{50} about 0.0003 μ g per insect, equivalent to about 0.03 mg kg^{-1}).

Recently, we synthesised insecticidal esters of 5-benzyl-3-furylmethyl alcohol¹ and 3-phenoxybenzyl alcohol^{2,3} with (1R, trans) 2,2-dimethyl-3-(2,2-dihalovinyl)cyclopropane carboxylic acids. (The nomenclature adopted here is a convenient alternative to that based on the sequence rule⁴ where, for example, the dihalovinyl acids formally derived from (+)-trans (1R, 3R) chrysanthemic acid by replacement of the vinyl methyl groups would be (1R, 3S)). The (\pm)-trans-dibromovinyl ester of 5-benzyl-3-furylmethyl alcohol has also been reported⁵. We have now prepared the corresponding (1R, cis) acids and esterified them with appropriate alcohols, including those of the α -ethynyl- (Belgian Patent 738112 to Badische Anilin-Soda-Fabrik Aktiengesellschaft and Ger. Offen. 2,230,862 to Sumitomo Chemical Company Limited) and α -cyanobenzyl (Ger. Offen. 2,231,312 to Sumitomo Chemical Company Limited) series. (1R, cis)-2,2-dimethyl-3-(2,2-dibromovinyl)cyclopropane carboxylic acid (Fig. 1b) was synthesised as shown via the aldehyde (Fig. 1a) derived from methyl (+)-cis (1R, 3S) chrysanthemate by an established method of ozonolysis (French Patent 1,580,474 to Roussel-Uclaf, S.A.). The ester (NRDC 156) with 3-phenoxybenzaldehyde⁶ cyanhydrin ((\pm)- α -cyano-3-phenoxybenzyl alcohol) (Fig. 1d) was very active as an insecticide. A solution of it in hexane deposited crystals after cooling for 2 months. Recrystallisation gave a single pure isomer (melting point 100°C, sharp; mass spectrometric molecular weight, 503; Br = 79) with an NMR spectrum showing only one signal for the CH(CN) proton of τ 3.64, whereas the parent mixture of isomers showed two signals of equal intensity at τ 3.64 and τ 3.72. The mother liquors contained material giving 2 signals (relative areas 1:4) also at τ 3.64 and τ 3.72.

TABLE 1 Toxicity of various insecticides to insects

Compound	Relative toxicity* to	
	Houseflies (<i>Musca domestica</i> L.)	Mustard beetles (<i>Phaedon cochleariae</i> Fab.)
Pyrethrin I	2.0	160
Bioresmethrin (NRDC 107)	100†	100‡

Dieldrin	35	4-10
(\pm)- α -cyano-3-phenoxybenzyl ester (NRDC 156)	1000	1000
NRDC 161 (crystalline component of above; see Fig. 1e)	2300	1600
Material in mother liquors from above crystallisation	350	380

* By topical application of acetone solutions as described previously¹, w/w basis.

† $LD_{50} \sim 0.006 \mu$ g per insect

‡ $LD_{50} \sim 0.005 \mu$ g per insect

Table 1 shows that the crystalline isomer (NRDC 161) was outstandingly active against insects compared with the non-crystalline form and with other insecticides. To mustard beetles, on a molar basis, NRDC 161 is twenty-four times as active as bioresmethrin^{7,8} (5-benzyl-3-furylmethyl (+)-trans-chrysanthemate, molecular weight 338) and fifteen times as active as pyrethrin I, the principal constituent of pyrethrum extract⁸. To a normal strain of houseflies NRDC 161 is thirty-four times as active per mol as bioresmethrin (itself more potent than most insecticides) and 1,700 times as active as pyrethrin I. The activity against houseflies was further enhanced by pretreatment (2 μ g per insect) with the synergist sesamex, which decreased the LD_{50} value from 0.00034 to 0.000018 μ g per insect (~ 0.002 mg kg^{-1}) (synergistic factor = 18, close to the value for less active synthetic pyrethroids⁹). The LD_{50} values for *A. stephensi* (ng per female) and *G. austeni* (ng per mixed sex) are respectively 0.036 and 0.08, giving an activity about forty-five times per mole that of bioresmethrin (F. Barlow, personal communication). The insecticidal activity of NRDC 161 and the effects of synergists are being studied further.

To obtain information about the absolute configuration of NRDC 161, (+)- α -cyano-3-phenoxybenzyl alcohol (optical purity, 95% from NMR spectrum of ester below) was prepared from 3-phenoxybenzaldehyde (Fig. 1c) and hydrogen cyanide in the presence of D-oxynitrilase¹⁰ (conveniently available in emulsion preparations, such as β -glucosidase, from Koch-Light Laboratories Ltd) and esterified with (1R, cis)-2,2-dimethyl-3-(2,2-dibromovinyl)cyclopropane carboxylic acid as in Fig. 1. The ester was not crystalline and resembled, in properties and insecticidal activity, material from the mother liquor after separating the crystalline isomer. If the (+)-cyanohydrin thus obtained from 3-phenoxybenzaldehyde has the same configuration as the D-(+)-mandelonitrile derived from benzaldehyde via the oxynitrilase¹⁰, the absolute configuration of the α -cyano-3-phenoxybenzyl alcohol in the potent crystalline isomer is S, for (+)-mandelonitrile is known to give (-)-mandelic acid, related to D-(+)-R-glyceraldehyde¹¹. The potent crystalline isomer, $[\alpha]_D + 15.6^\circ$, is therefore tentatively assigned the structure [S]- α -cyano-3-phenoxybenzyl cis-(1R,3R) 2,2-dimethyl-3-(2,2-dibromovinyl)cyclopropane carboxylate (Fig. 1e) pending determination of the absolute configuration by the X-ray examination (now in progress by Dr J. D. Owen and Dr M. R. Truter).

The discovery of a pyrethroid with such great toxicity to insects and atypical activity in mammals (see accompanying

FIG. 1 Synthesis of the active compound.

paper¹²) has important theoretical and practical implications, now being examined.

The new compounds are protected by UK Patent Applications Nos 20539/73, 39539/73 and 49098/73 and corresponding foreign applications.

We thank Dr J. Martel (Roussel Uclaf SA) for a generous gift of (+)-cis-chrysanthemic acid, Dr J. M. Barnes, Mr R. D. Verschoyle and Mr F. Barlow for results and discussions, and the National Research Development Corporation for financial support.

Toxicity of new pyrethroid insecticide

THE mammalian toxicity of NRDC 156 and NRDC 161 (see accompanying paper¹) was assessed in albino female, rats 10 to 12 week old.

Given as solutions in glycerol formal by the intravenous route, the lethal dose of NRDC 156 was 6 to 8 mg kg⁻¹ and of NRDC 161, 2 to 2.5 mg kg⁻¹. Orally, as solutions in arachis oil, an LD₅₀ could not be computed, but the rats showed severe toxic effects, with some deaths in the dose range 80 to 160 mg kg⁻¹ for 156 and 25 to 63 mg kg⁻¹ for 161.

The signs of poisoning in these rats were not the same as those described for other pyrethroids². The first sign was excessive salivation without lachrymation, rapidly followed by continuous irregular jerking movements of the limbs, progressing to rolling convulsions, and an occasional tonic-clonic convulsion. Death occurred from 12 min to 2 h after intravenous dosing and from 3½ to 28 h after oral dosing. Survivors were usually almost normal within 4 to 6 h after intravenous dosage, but recovery from an oral dose took up to 48 h.

The impression gained from observing the animals was that the site of action of NRDC 156 and 161 was mainly central, with little or none of the peripheral component that has been demonstrated for other pyrethroids.

First frog fossils from Australia

RECENT speculation about the ancestral frog fauna of Australia, even embracing the Cretaceous¹, has been based purely on zoogeographic deductions, for study of the origins and history of this fauna has been seriously handicapped by the complete absence of an endemic fossil record. Although it has been suggested^{2,3} that the Lower Eocene *Indobatrachus* of the Intertrappean beds of Bombay represents the Australian leptodactylid subfamily Myobatrachinae, such a relationship is considered dubious or untenable by other authors^{4,5}. It is therefore of interest to report the recent discovery of isolated fragments of frog bones among a rich mid-Miocene vertebrate fauna in Central Australia, so being the first frog fossils found in Australia.

The material was obtained at Tedford Quarry, V-5375, on the west side of Lake Palankarinna in the extremely arid north of the State of South Australia. The site is in the Etadunna Formation, and the biological material recovered there is termed the Ngapakaldi Fauna by Stirton, Tedford and Woodburne⁶.

Most of the isolated anuran bones comprise limb fragments (particularly heads of humeri and femora) which, at present, cannot be referred to families, but there is included an almost complete left ilium (Fig. 1) which is 7 mm long and remarkably well preserved. This specimen is of particular value because of all isolated anuran bones the ilium is considered to be of the greatest diagnostic value at the familial, generic and even specific level^{7,8}. The fossil is, however, so unusual that its familial disposition is not readily resolved.

Four families of frogs are currently recognised from Australia: Hylidae, Leptodactylidae, Microhylidae and Ranidae. Nevertheless, the disjunct distribution of the Leiopelmatidae now confined to North America and New Zealand indicates that leiopelmatids may have formerly occurred in Australia. Hence it would be unwise to restrict comparative osteological studies to families now represented.

FIG. 1 Left ilium lacking only the proximal portion of the shaft and the distal tip of the dorsal acetabular expansion. (Photo: R. Wood.)

What makes the fossil so noteworthy is the presence of a deep lateral groove extending on the length of the ilial shaft. Modifications to the shaft certainly occur in several modern families, but such modifications inevitably involve the development of ridges or crests extending above the body of the shaft. In many ranids the crests are particularly well developed.

The moderate development and lateral disposition of the dorsal prominence is consistent with Lynch's³ observations on Australian leptodactylids, but the acute angle at which the ventral acetabular expansion subtends to the ilial shaft is contrary to Lynch's definition of 90°–110° and my own observations (90°–130°). Provisional studies, however, favour the assumption that the fossil will ultimately prove to be a leptodactylid or possibly a hyliid. Trueb⁹, the most recent contributor to revisionary studies of the anuran ilium has already summarised the criteria that support this contention, namely that primitive anurans "have a plain shaft that tends to be cylindrical in cross section". It has been argued by Tyler¹⁰ that the Microhylidae and Ranidae probably colonised Australia no earlier than the Pleistocene. Bearing in mind the duration of the isolation of Australia, it seems likely therefore that the Miocene fauna was composed solely of hyliids and leptodactylids, and possibly a perpetuated remnant of the ancestral stock from which these Australian frogs are derived.

That the Ngapakaldi Fauna is only of mid-Miocene age, relies upon the palynological evidence of W. K. Harris (personal communication), for Stirton, Tedford and Woodburne⁶ consider it late Oligocene or early Miocene. The environment occupied by the Ngapakaldi Fauna, as indicated by its content, was certainly less inimicable to anurans than the current aridity, and it follows that it is reasonable to anticipate little similarity between the Ngapakaldi anuran Fauna and the arid-adapted fauna now occurring in the extreme north of South Australia.

I thank Dr M. O. Woodburne for the opportunity to examine this material. Description awaits the completion of more detailed comparative studies.

book reviews

Chemistry to build reactors

The Chemistry of Fusion Technology. Edited by Dieter M. Gruen. Pp. xiv+394. (Proceedings of an American Chemical Society Symposium held in Boston, Mass., in April 1972.) (Plenum: New York and London, 1972.) \$22.50.

THE possibility of creating conditions in which the nuclear energy of light elements might be released in controlled nuclear fusion reactions emerged from the advances in nuclear physics in the period 1930–50. To bring these ideas to fruition, it has been necessary first to establish a major new branch of physics, high temperature plasma physics; second, this new knowledge has to be applied to potentially practical systems; and third, the technology of such systems has to be established.

With the growing progress in plasma physics and in its application to the magnetic confinement of high temperature plasmas (a turning point was the publication in *Nature* of the results of the joint Soviet–United Kingdom experiments on the Russian Tokamak magnetic confinement device in 1969) and with a growing awareness of the acute nature of the potential energy shortage, much more interest is being shown worldwide in the third area—the technology of future fusion reactors. Since very large resources have been accumulated over the years in nuclear fission technology, there is no shortage of experienced and resourceful researchers able and anxious to tackle the new technological challenge: and it is now possible for the energetic student to attend perhaps half a dozen symposia a year in which the problems of the technology of fusion reactors are scanned and discussed. Moreover, large sums of money are forecast to be available, particularly in the United States and Germany, to tackle what in 1946 George Gamow described as a problem of almost unsurpassable technical difficulty.

The present volume is a record—and a good one—of one of the most constructive of such symposia. It discusses, at a foundation level, the problems of chemical engineering which will have to be dealt with if the current physical idea proves correct: that controlled fusion reactors will be fuelled by deuterium and lithium and based on thermonuclear reactions between deuterium and tritium in an isolated high temperature

plasma. No particular system of plasma confinement or control is envisaged, so that the meat of the volume is of value whichever of the current systems advocated on physics or engineering grounds turns out to be the most practicable.

J. D. Lee of the University of California is a leading authority on the breeding of tritium in the lithium-bearing blankets, and his article (40 pages) on tritium breeding and direct energy conversion summarises authoritatively the main results of his group on neutronics of the blanket, together with short discussions of the chemical and electrochemical problems of using liquid lithium metal as a coolant in a high magnetic field. The section on direct conversion is, disappointingly, confined to a secondhand presentation of one particular system—the direct conversion of the mirror energy leakage, by R. F. Post. The review of the chemical, physical and thermal properties of lithium (70 pages, 111 references) by Cairns, Caffasso and Maroni of the Argonne National Laboratory, is a fundamental and authoritative collation of data particularly valuable because of critical assessment of the data and the extensive bibliography; it includes data on topics ranging from natural abundance, thermodynamics and physical properties to corrosion rates of selected high temperature materials in lithium. Likewise, W. R. Grimes and S. Cantor of Oak Ridge on the use of molten lithium-bearing salts as coolant and breeder (28 pages, 36 references) cover important data on one of the major alternative constituents of the blanket, and their article is based on Oak Ridge experience of the Molten Salt Reactor. E. F. Johnson of Princeton—another leading authority—deals (22 pages, 21 references) with the chemical problems of tritium extraction from the blanket, but rather too briefly and qualitatively to be of lasting value. His article does, however, give a useful summary of the Princeton reference design model reactor which provides the non-specialist reader with a concrete example of present-day reactor concepts.

D. M. Gruen provides a useful and interesting account (24 pages, 57 references) of the often-neglected chemical effect of plasma interaction with thermonuclear reactor surfaces, together with a brief review of more familiar surface topics. R. E. Stickney provides a major

and critical account (78 pages, 110 references) of the permeation of hydrogen isotopes through high temperature materials—a matter of great importance to the assessment of the spread of tritium around and through the components of envisaged reactors. Finally, the chemical content of the volume is completed by a short (16 pages, 31 references) article by G. G. Libowitz on condensed-metal hydrogen systems, and a rather superficial article on superconducting materials.

To the fusion reactor specialist, the main value of the book rests in the bringing together of today's main chemical knowledge relevant to fusion reactors, or at least fusion reactor blanket systems. To the chemist, the book indicates the main areas of chemical technological interest provoked by current fusion reactor concepts. The impression for the non-specialist is likely to be that each individual problem of chemical technology so far raised and discussed has outline solutions, but the sum total of the problems constitutes a serious technological barrier which—as in the case of fission reactors—can seem daunting in the initial stages. There is clearly a great need to improve much of the chemical data and understanding, particularly in the difficult areas of corrosion (where the effects of trace elements are not understood), permeation and radiation chemistry.

R. S. PEASE

Solid electrolytes

Physics of Electrolytes. Edited by J. Hladik. (Transport Processes in Solid Electrolytes, and In Electrodes vol. 1. Pp. xiii+516. (Academic: New York and London, August 1972.) £11.00; \$34.

THIS series of review articles was presumably intended to provide the background knowledge required for investigating the properties of ionically conducting solids, a field which is currently attracting considerable interest. The topics covered in this volume are grouped into two sections; "Solid Electrolytes and Electrodes" and "Transport Processes".

The first section contains a rather heterogeneous collection of articles. In the first two chapters, Hladik discusses electronic theories of the solid state, interatomic distances, the cohesive energy in ionic crystals and also gives a gen-

eral account of solid electrolytes. Unfortunately, the relevance of many of these topics to the study of solid electrolytes is not made clear. The discussion of interatomic distances is rather inconclusive and that on cohesive energy suffers from a lack of references to the tabulated data; this is particularly irritating when the data in two tables (X and XII) do not agree.

Fong has contributed an account of the statistical mechanical treatment of interactions between impurity atoms and lattice defects in ionic crystals, and the experimental results available to test this theory. In the final chapter of this section, Amsel describes the range of applicability of, and some of the experimental results obtained with nuclear microanalysis. This chapter makes extremely interesting reading but deals mainly with film formation on metal surfaces.

The section on transport processes is much more homogeneous. Friauf gives a sound account of the basic theory of conduction and diffusion in solids and describes the methods available for determining the mechanism of these processes. Diffusion processes are also clearly discussed, though in more detail, by B  ni  re but there is considerable overlap between these two chapters; some of the tables and figures and much of the theory being common to both. B  ni  re has also contributed a good but incomplete account of transference number measurements in ionic crystals. The measurement of the transference number of the electron by EMF measurements or by the Wagner technique is unfortunately not described. Ionic conductivity in solids is reviewed by Kvist but only a cursory account of the experimental methods and the conditions which must be satisfied in making conductivity measurements is provided.

The remaining chapters by Hartman, on ionic conductivity in whiskers, Hughes and Isard, on ionic transport in glasses, and Riande, on transport phenomena in ion-exchange resins, are very competent reviews.

Overall, this book suffers from inadequate editing to remove the unnecessary overlap between some chapters and to provide the links between the separate contributions. The proof reading, especially of the chapters by Hladik, must have been careless and should have ensured that the tables and diagrams in the chapter by Kvist appeared nearer to the relevant sections of the text.

In spite of the limitations described above, this collection of articles and especially those on transport phenomena, should be of value to those involved in this area of research.

T. DICKINSON

Copernicana

The Scientific World of Copernicus: On the Occasion of the 500th Anniversary of His Birth, 1473-1973. Edited by B. Bienkowska. Pp. xii+142. (Reidel: Dordrecht and Boston, 1973.) Dfl. 50.

1973, half a millennium since the birth of Nicholas Copernicus the founder of modern astronomy, has produced an unprecedented outpouring of Copernicana. To the present example twelve authors contributed essays, three previously published in Polish and one in French.

Discrepancies between statements by different contributors have been overlooked by the editor. Thus Copernicus is said to have spent "five years as [a] student in Cracow" (page 1). Yet "Copernicus enrolled at the University of Cracow in 1491. For the four years he remained at the University he devoted himself to the study of the liberal arts without, however, winning an academic degree" (page 15). Was Copernicus at Cracow four years or five? The university records do not reveal when he left. At Cracow the bachelor's degree was normally obtained in four years. Surely the founder of modern astronomy was no dullard. Since Copernicus received no degree from Cracow, and did not need the baccalaureate for the career which he contemplated, presumably he stayed less than four full academic years in Cracow.

Readers are assured that the thesis of Copernicus' *Revolutions* "was accepted . . . without demur by Pope Paul III, to whom Copernicus' book was dedicated" (page xi). For this familiar assertion about the reigning pope, nobody has ever adduced any documentary support. Evidence to the contrary was published in *Rivista critica di storia della filosofia* (26, 84-85; 1971). Shortly after Copernicus' *Revolutions* was printed in 1543, initiating modern astronomy and therewith modern science, preparations to condemn that magnificent work were begun by Pope Paul III's personal theological advisor, Bartolomeo Spina; the Master of the Sacred and Apostolic Palace. But before Spina could act, he fell ill and died. Thereupon Spina's close friend Giovanni Maria Tolosani resumed the theological anti-Copernican campaign in an appendix to his treatise *On the Truth of the Holy Scripture*. Herein Tolosani declared that Copernicus "contradicts some Scriptural principles, not without danger of infidelity both to himself and to the readers of his book". An annotation in Tolosani's manuscript discloses that his attack on Copernicus "for the purpose of safeguarding the truth to the common advantage of Holy Church" was later consulted by the preacher of

the first public sermon against that great Copernican, Galileo.

The (lost) reconciliation of Copernicanism with the Bible was written by Copernicus' disciple Rheticus, not by Bishop Giese (page 27). The "first publisher" of Copernicus' *Revolutions* was Petreius, not Osiander (page 140).

EDWARD ROSEN

Chromosome more or less

Cytogenetics of Aneuploids. By Gurdev S. Khush. Pp. xii+301. (Academic; New York and London, December 1973) \$17.50: £8.40.

THIS book is a survey of what has been achieved in isolating, identifying and using aneuploids, that is, individuals whose chromosome number differs from an exact multiple of the basic number. Most of the book is concerned with aneuploids in plants, with a very short chapter in which the author briefly describes examples of aneuploids in animals, especially man.

After outlining concisely the history of the discovery and production of the various aneuploids, and the terminology used for the different types, the author gives a very useful glossary of the current terms, and an explanation of the chromosomal formulae used to indicate the different types of aneuploids.

The book is then divided into two main parts, the first dealing with trisomics, with some mention of tetrasomics, and the second dealing mainly with monosomics but also mentioning nullisomics. As monosomics and trisomics have seldom been developed in the same species, this does not lead to too much duplication, and the two sections are linked by cross references where necessary. Each part covers the sources of the relevant aneuploids, detailing how the various types have been obtained in different species; some of the difficulties encountered in producing the aneuploids; the cytological behaviour associated with the aneuploid condition; and the breeding behaviour of the aneuploids. There are chapters on the uses of aneuploids, which include chromosome mapping, locating markers on chromosomes, locating the centromere and orientating the linkage map on the chromosome, as well as the production of substitution and addition lines.

The book brings together data widely scattered in the biological literature, and so will be a valuable reference work for those wishing to develop or use an aneuploid series, as well as being a useful source of information for anyone requiring a basic knowledge of the subject. It will therefore be of use to honours undergraduates as well as practising cytogeneticists and plant breeders.

J. P. MOSS

Full attention

Attention and Effort. By Daniel Kahneman. Pp. x+246. (Series in Experimental Psychology.) (Prentice-Hall: Englewood Cliffs, N.J., July 1973.) \$8.95.

BETWEEN the wars the topic of attention was neglected by psychologists, in their enthusiasm for predicting each response as a function of the immediately previous stimulus. The difficulty was, however, that the effects of a stimulus depend upon the state in which a man is when he receives it. Sometimes he reacts to it, will say verbally that he has noticed it, will remember it later; and sometimes none of these things will happen. The processes which can be variously and roughly described as gating, filtering, or selecting among inputs to the system have therefore become a live area of research: and books on attention are now almost too numerous. They range from the massive, detailed, and unreadable to the popular, chatty and superficial. The competition for another is tough.

It is a pleasure therefore to be able to declare this book the best one on the subject thus far. It is short, clear, and extremely up to date: not merely are there references to publications in 1973, but also exciting accounts of new experiments by the author and his students in Jerusalem, which will be carefully read by advanced workers in the field. At the same time, the coverage of the literature is wider than in most of the competitors, and the author understands sympathetically what is being argued by other investigators. Thus for once this is a book which can be recommended, not only to the advanced workers already mentioned, but for teaching purposes, and even conceivably for non-psychologists who wish to find out the latest state of the art in this area.

For those who are already expert, one can indicate the position the book adopts by saying that it takes broadly the position of Treisman, but with much greater emphasis and experimental detail on Neisser's pre-attentive processes, and on recursive influences from processes at one stage of recognition upon others both earlier and later in the system. The findings of the past two or three years make it possible to do this convincingly and briefly, and Fig. 5-1 is perhaps the first diagrammatic representation of attention which improves upon that of Treisman in 1960.

Criticisms? The book is weaker when it turns to motor performance rather than perception, which is reasonable because the state of knowledge is less satisfactory: and there are perfectly adequate references to Posner, to Keele,

to Brown and to Trumbo and Noble for those who wish to go further. Those of us who work on the effects of noise and of other stresses will be discontented by the way in which effort, arousal, the allocation of resources and the process which determines the size of the pupil are all treated almost interchangeably. Perhaps one can most fairly put it this way: there are real differences, which experimental evidence compels us to draw, between easy and involuntary attention such as that with which we follow the graceful prose of this author; and the determined concentration, sustained by a hope of remote goals, with which we mobilise all our resources to follow the confused thinking of some others. These differences are not yet understood, but for what we know now, Kahneman is the best guide.

DONALD E. BROADBENT

Nematode interactions

Nematode Ecology and Plant Disease. By H. R. Wallace. Pp. ix+228. (Arnold: London, December 1973.) £6.50.

THIS is a readable and interesting account of nematode ecology and the role of nematodes in plant diseases. Early chapters discuss nematode injury to plants, plant growth in relation to numbers of nematodes and plant responses to nematode invasion and feeding. The second half of the book deals with distribution, abundance and adaptations of plant-parasitic nematodes in the environment and with their involvement in specific diseases. The final chapter suggests how the role of nematodes in plant diseases should be investigated.

Unlike Dr Wallace's earlier book (*Biology of plant-parasitic nematodes*; 1963) this is no textbook; for it is far from comprehensive and the references are nearly all drawn from the last decade. The text is often speculative, not a bad thing, but it is also at times superficial, and with some conclusions that are debatable. The book is best where, as in parts of the chapters on nematode ecology, it deals concisely with its subject. Too much of the text, in my opinion, is taken up with fulsome descriptions, definitions and debates on abstractions such as 'health', 'disease', 'homeostasis', and ecological jargon and with the views of medical and plant pathologists.

Too little attention is devoted to well documented evidence of the relationship of nematodes with plant diseases. For example, much is known of nematode-fungus interactions in plant disease complexes and of nematodes as vectors of plant viruses, both of which receive scant attention. The inferences drawn about the work on Docking disorder are incorrect. Nor does Wallace indicate

how much can be learnt from careful study of plant symptoms and from inoculation experiments with suspected pathogens.

Instead, he stresses the use of multifactorial analyses of all the environmental variables that can be thought of and measured, to indicate which factor or combination of factors is most likely responsible for the particular disease. To my mind this is putting cart before horse. Not all diseases involving nematodes are as complex as Dr Wallace implies or we would be without commercially successful cultivars bred for resistance to specific nematodes. Despite such criticisms I commend this book to all thoughtful nematologists, plant pathologists and ecologists.

A. G. WHITEHEAD

Physicists talking

Fundamental Interactions in Physics: 1973 Conference at the Centre for Mathematical Physics in the University of Miami. Edited by Arnold Perlmutter. Pp. ix+399. (Studies in Natural Sciences vol. 2.) (Plenum: London and New York, 1973.) \$29.

A CONFERENCE on so wide a subject as this one is in danger of losing coherence and producing a set of papers from so great a range of disciplines as to require from any one scientist an enormous effort of comprehension, and yet to include contributions so speculative as to make such effort unworthwhile. This familiar danger is avoided by the present volume, largely because of the elegance and informality of the presentation of the papers which seem to have been presented as talks and recorded verbatim. Here, perhaps, is a solution to the problem of scientific style on which John Maddox commented in a recent BBC radio broadcast: "... when a scientist sits down in front of his IBM typewriter. . . ."

There are three sections in the book. The first deals with particle physics and is largely theoretical though it includes an informal description of work at the National Accelerator Laboratory (Batavia, Illinois) and a paper by Hofstadter on applications of absorption detectors. The theoretical papers range from a quasi-classical discussion by P. A. M. Dirac of symmetry breaking, in a new variation of Weyl's theory of the electromagnetic field, to a terse and wholly algebraic "Approach to Hadron Physics . . ." by Oneda and Matsuda. Several of these papers contain much that is new, and some of them contain fertile ideas rather than completed theories. For example, Bopp and Lutzenberger in a short contribution throw out a simple model of quantised retarded forces in which the electron and the muon appear as eigensolutions sub-

Biology of Development

*An integrated, self-instructional,
programmed Audio-Visual Course*
Under the Editorial Direction of
Dr Gaye Manwaring

*Departments of Education and
Biology University of Glasgow*

This course is designed for sixth forms, technical colleges and first year classes in universities and polytechnics. The course consists of 15 programmes each comprising a tape, a full-colour filmstrip, a workbook and a teachers' guide book. It provides the basic facts necessary to understand the types of changes that occur during development; the methods by which such phenomena are studied; current ideas about control mechanisms and their biological significance.

The programmes are an extremely flexible teaching aid, ideal for use with mixed ability groups and with students from varying academic backgrounds.

Contents

Cells and organisms - Cells in Action - Mitosis - Meiosis - Fertilisation - Cleavage - Gastrulation - The formation of organs - Developmental plant physiology - Growth - Nucleus and cytoplasm - Hormones - Regeneration and Development switches - Shape and pattern - Embryos and larvae.

For further information about this course please write to:

The Promotion Co-ordinator,
Room 502, Longman House,
Harlow, Essex CM20 2JE

Longman
1724 - 1974

ject to the correctness of guesses about the bare masses and angular momenta of the particle in their model. But at least three of the papers (by Kur-sunoglu, Salam and Blokhinstev) have a more didactic purpose and will be of great use to graduate students of particle physics.

The papers in the second section on atomic and molecular physics, one by Massey, one by Spruch and one by Herzenberg, are nearer to reviews than those in the first, but there are also two panel discussions. Three more speculative papers on X-ray astronomy, helium and biology make up the third section.

Despite the relatively high speed of the book's production the presentation is excellent and free of misprints. Thus a scattered but uniformly high powered, original but well written collection of papers make up a book which particle physicists will find stimulating and informative. I hope that university libraries (to whom the high price presumably restricts the book's sale) will make it available to them.

PHILIP ROE

Thinking protozoa

The Evolutionary Foundations of Psychology: a Unified Theory. By Felix E. Goodson. Pp. xi+228. (Holt, Rinehart and Winston: New York and London, 1973) n.p.

Dr Goodson sets himself the Kantian goal (the parallel is mine) of effecting a transcendental deduction of the psychological factors necessarily involved if the evolution of complex organisms is to be possible. In other words, he aims for an integrated view of psychology derived by way of abstract arguments from a broadly evolutionary base.

Unfortunately, although he has some interesting things to say about the psychological necessities inherent in the earliest forms of life, his concepts are not sufficiently structured or precise to add much to one's understanding of mammalian and human psychology. To be sure, his stress on adaptive function for the sake of the organism as a whole is preferable to an excessively narrow conception of psychology that ignores man's evolutionary context. And he relates a wide variety of findings in empirical psychology to this overall perspective. But his remarks are too vague to be helpful, and leave most interesting substantive questions unanswered—or, worse, unasked.

For example, he identifies the paramount task of psychology as "an evaluation of apperception that focusses on the variables that affect the rapid shifting from one component to the next", where by "apperception" he means the process (often called "attention") by which inputs from the senses or the

memory come briefly into focus in the conscious mind (page 68). Whether or not accounting for the detailed course of the stream of consciousness is 'the' paramount task of psychology, it certainly is an important psychological problem. But what does Dr Goodson have to say on the subject?

"Thinking", he says, "is nothing more than fluctuation of apperception among available encodes and as such is a completely automatic and lawful process" (page 135). Readers of *Nature*, who are not prone to think of thinking as a random activity, can hardly demur with this—but what one wants is some indication of the nature of the laws involved. Precise specification, of course, is not to be looked for in a deliberately general and abstract discussion. But one might reasonably hope for a more powerful concept than "equilibration" (which is involved in Goodson's most basic "evolutionary postulates of process") an indication of the psychological complexity of thought. Thus the characterisation of "thinking" quoted above continues: "Apperception is always the most equilibratory response possible to the myriad components dynamically interacting within the integration matrix, and when the components brought into sequential focus consist of encodes, thought is taking place".

If a generic concept of equilibration is to be applied equally to the specifics of chemical diffusion in protozoa and flights of fancy in human beings, more needs to be said about the differential aspects of the phenomena so confidently classified together. Even the social psychological theories of "cognitive consistency" and "cognitive balance", vague and unsatisfactory as they may be, make a better attempt than Goodson to state what constitutes "equilibration" in differing types of thought. Equally, Freud offered more substantive suggestions about the structure of the "integration matrix" and the varieties of "psychic disequilibrium" than can be found in this book. It is ironic that Goodson castigates psychoanalytic theory for "its reliance on vague terminology" (page 204).

I should perhaps admit my own conviction that the complexities of mental structure can only be satisfactorily approached by way of the concepts currently developing within artificial intelligence. My dissatisfaction with this book doubtless reflects the measure of its distance from this theoretical approach. But I think it unlikely that psychologists favouring other paradigms would find it a rich source of insights. Even Kant tried to show in detail how specific examples of human thinking (such as the metaphysical antinomies) were generated by the abstract forms of thought postulated by his transcendental deductions. MARGARET A. BODEN

science on radio

Bush House bonanza

John Gribbin and Eleanor Lawrence

One of the strangest economies proposed in the latest round of British belt-tightening is to cut back drastically on the funds available to the external services of the BBC, which operate from Bush House, London. These services have already suffered a small decline in the amount of cash available to them—which represents a significant decrease in real terms, after inflation has done its worst. Yet the BBC continues to be held in the highest esteem by listeners around the world, who find its services informative and, relatively, free from propaganda. Of course, even the BBC is not completely unbiased: its science, industry and agriculture unit, for example, makes no bones about the fact that although it hopes to report fundamental developments in pure science wherever they are made, technological applications with commercial applications are generally only 'promoted' if they are British. But that understandable bias is hardly in the same league as the political propaganda of the other giants of world broadcasting.

Compared with the domestic services of the BBC (and, indeed, the internal broadcasting services of other countries) Bush House provides a veritable scientific bonanza. Out of 168 hours of broadcasting in English each week, there are two half-hour programmes devoted entirely to science (each of them repeated twice), a nature notebook and a programme for farmers. With more or less regular scientific features (12 to 20 a year, each running for 30 minutes) and the tit-bits of science found in news and current affairs programmes, the total is something like 5 percent of the weekly output.

This is achieved with a very restricted budget, roughly half of the amount available for comparable domestic programmes (such as the late, lamented "Kaleidoscope"); if the funds of the science unit are cut back at all there seems no way in which economies could be made except by reducing the number of programmes. It may not happen, and it certainly should not happen, to judge from the quality, as well as the quantity, of these programmes.

Of the two main science unit programmes, "Science in Action" aims "to inform and sometimes amuse" the non-

specialist listener. We were a little surprised by the high scientific standard of this programme—but of course it is broadcast in English, and therefore its audience overseas must be better educated and more well-informed than the average population. Audience response and a recent survey indicate that medical items are most popular, with communications and astronomy following some way behind. Questions asked by listeners indicate how successfully the programme communicates with its intended audience: would two children brought up together in isolation from birth learn to communicate and what are hypertension and vertigo?

At a high level, "Discovery" aims to be by scientists and for scientists, and beats anything else we have heard on domestic radio or elsewhere hollow. In the half-hour programme, two or occasionally three scientists are interviewed about their own work and given free reign. The result is something like a radio version of the "News and Views" section of *Nature*.

In one programme we heard, Dr V. Marks from the University of Surrey talked about gut hormones and insulin control, and Dr Jeffrey Manning from the Rutherford Laboratory explained their current accelerator research programme. This did not duck what seemed to us the contentious question—especially to an audience in the developing countries—of whether an accelerator costing £15 million is justifiable. But it seems that there is, in fact, a more general recognition of the value of fundamental research in the countries which can least afford it themselves.

This raises another interesting point: the lively postbag received by the science unit includes contributions from the poorest countries, where the cost of posting a letter to Britain can be as much as 50 percent of a week's earnings, yet many listeners feel it worth the cost of responding in this way. One correspondent, an Indian doctor, said how much he valued the programmes as his only effective means of keeping up to date, since the cost of "the literature" is quite prohibitive for him.

Part of this listener interest must stem from the immediacy of the programmes. Special features, such as one discussing the causes and implications of the present droughts in sub-Saharan Africa, can be put together within 72

hours, and in a "Science in Action" programme broadcast in the week ending April 6 Dr Simon Mitton, of the University of Cambridge, could be heard giving details of the Mariner-10 observations of Mercury which were certainly new to us. This immediacy is aided, of course, by the happy relationship between Bush House and active scientists, who are, it seems, often pleasantly surprised at the difference in approach between the external services and the domestic TV services.

As well as the programmes broadcast from London, the BBC also provides a service for radio stations around the world in the form of taped programmes. And this really is a service—a weekly fifteen minute tape programme, for use intact or to be cut up and inserted into other programmes, costs only £1.50 plus postage, and there is no obligation for the user even to credit the BBC when an item is used. One of these tapes, "Science Magazine", has a link with *Nature* in the form of a weekly contribution from one or more members of the editorial staff: this programme is a mixture of short items and a long interview, almost a combination of "Science in Action" and "Discovery". It has not always come off as a programme in itself, although at the giveaway price excerpts find outlets around the world, not just in developing countries but also on American public and campus radio. We have, however, heard a pilot of a 'new look' "Science Magazine", with more punch and a lively signature tune: this format seems more likely to provide a good listen and makes more sense for users who wish to broadcast the programme intact.

All in all, the science output from Bush House is difficult to fault. The fundamental reason for this seems to us to be that the producers themselves and most of the presenters all have scientific training, although the audience is not entirely science oriented, as correspondence from insomniacs and long distance lorry drivers in Britain indicates. Far from reducing this valuable output, the powers that be should be encouraged to promote it as a valuable string to the BBC's bow, in the best traditions of Reith. Perhaps they could even take note of the most common plea from those insomniacs and list the programmes, in as small a print as they like, in the *Radio Times*.

instrument review

Surround sound

John Wilson

IN an attempt to capture both the natural direction and reverberation of sound in a live performance, Professor Peter Fellgett of the University of Reading and Michael Gerzon, an Oxford mathematician, are developing a new 'ambisonic' hifi system in association with IMF, a British loudspeaker manufacturer. The National Research Development Corporation holds the patents for the system and is backing the project financially.

The new technique improves on present quadrasonic systems because of its ability to present natural sound images between the front and rear pairs of speakers, and to reproduce sounds which seem to arise either between the listener and a loudspeaker or beyond it. Indeed Mr Gerzon believes that: "Quadrasonics, as at present widely conceived, is a dead end."

Unlike the conventional quadrasonic approach, where a separate channel is so often deemed necessary for each loudspeaker, the new ambisonic system uses information from a multidirectional microphone array encoded on just two channels. This should lead to the complexities and sophistication of surround sound techniques being relegated to the recording studio and not to the living room. Indeed, apart from two extra loudspeakers, suitably in phase, only a decoder will be necessary to convert an ordinary stereo system.

This new approach should not be confused with the so-called 'matrix'

systems where information from conventional microphones is artificially blended to achieve an approximation of surround sound. With ambisonics, sound from every direction reaching the tetrahedral microphone array is treated equally until the decoding operation.

Michael Gerzon, who Professor Fellgett feels should take most of the credit, points out that an ambisonic system is not limited to four loudspeakers, although this is the number which is most attractive commercially. Since the microphones also pick up the sounds coming from above and below them, these too may be reproduced if six or more loudspeakers are used with the appropriate decoder. Three is the optimum number of channels for four speakers (and therefore fm radio transmission), five channels for six loudspeakers, six for seven and so on. The position of the loudspeakers must be very carefully worked out because they are not in the usual planar arrangement.

Nature hopes to publish an article describing the mathematics behind the new system in the fairly near future; but how does it sound in practice? The new system was demonstrated at the recent Sonex 74 exhibition in the Post House Hotel near London's Heathrow airport. Four expensive monitor speakers were supplied for the occasion by IMF but the signals themselves came from an ordinary Philips cassette.

Just before the demonstration began, a director of IMF, Mr John Wright, said a few words of warning about the acoustics in the demonstration room. He should have said more because the organisers could hardly have picked a

worse spot. One wall of polished mahogany bounced the sound like a mirror through an acoustically transparent partition opposite and even the other, more normal, wall was faced by a large window with heavy, absorbent curtains. So the demonstration was rather disappointing, particularly regarding the claim that the nearer a listener is to particular speaker, the less sound he is conscious of hearing from it. This simply could not be true in a room where the sound was escaping next door through one wall and being smothered in the curtains of another.

In spite of this one or two of the selections on the tape gave some idea of what an ambisonic system is capable. In particular, a fine piece of organ music produced the strong impression of being in an echoing church. Considering the real surroundings, this was no mean feat and Professor Fellgett said that he hopes to arrange another demonstration in a more suitable location.

The technique is still very much in the experimental stage, with new directional microphones being developed, for example, and the inventors emphasise that they have no plans yet to market it themselves. Rather, they wish to attract the attention of recording studios and manufacturers with a view to licensing their invention—much in the same way as Dolby has licensed his method for 'stretching out' the hiss from tape recordings. In this respect Professor Fellgett says that IMF is acting like "the good farmer" by seeking to develop the system for the benefit of all, although it naturally has a commercial interest in being in the forefront of a new technique.

matters arising

The information problem

SIR,—K. L. and M. L. Blaxter, in their article *The individual and the information problem* (*Nature*, 246, 335) make some incidental remarks which cannot pass unchallenged. They say, for example, that the "so-called information explosion . . . apparently causes consternation to librarians, archivists and information scientists". No evidence is quoted

in support of this suggestion, perhaps because it would be difficult to come by. Whatever consternation exists is, in fact, more likely to be found among the ranks of the users than of those of us professionally engaged in dealing with the problem. We are far too busy actually harnessing the forces of the information explosion to have time to strike attitudes of consternation.

Bryan¹ summed up the viewpoint of

many librarians when he argued that the information problem is essentially a users problem, and not primarily a technical problem. The remark is also unfortunate in that it seems to imply an inactivity in the face of crisis; a glance at, for example, the current issue of *Library and Information Science Abstracts* may help to dispel this misconception. Most of the Blaxters' findings are already well known to librarians, and we need no convincing

as to the desirability of such things as the application of objective criteria to the purchase of periodicals. At least one university library, Surrey, is now basing its periodicals purchasing policy on studies of use², and the possible use of such aids as the Institute of Scientific Information's *Journal Citation Reports* is being actively examined in other libraries. Secondary journal citation is another approach being studied³.

It is also suggested that for a scientist to admit that he could not keep abreast of his own speciality would imply an incompetence. There is a confusion here between two separate and distinct areas of competence; competence as a scientist in a particular field of science, and competence as an information searcher. These two abilities are different, and the first does not necessarily imply the second. Many writers have commented on the difficulties encountered by scientists in using the literature⁴⁻⁸, and some scientists are prepared to admit their limitations in this field⁹. If past work is to be fully utilised, and duplication avoided, it is essential for all scientists to be aware of their own personal limitations, and to seek whatever assistance they require from professional information workers.

As long as there remain scientists who regard it as somehow *infra dig* to ask for advice or help on information problems, then some at least of these problems will be of their own making.

Yours faithfully,
D. M. SALTER

The individual and the information problem

SIR,—Blaxter and Blaxter raise a number of interesting points in their recent paper (*Nature*, 246, 335; 1973). They are careful to emphasise that their results and conclusions obtain from the views and habits of full-time research

scientists working in three biological research institutes, and that these may well differ from those of university lecturing staff, with educational commitments in addition to those of research. I should like to comment here on just one conclusion from the Aberdeen survey, however, and suggest that it may indeed be more generally applicable.

The Blaxters were able to estimate a figure for the total number of journals to be taken by a research institute's library to give 90% satisfaction to 90% of its users, a figure which was 25 times the number of 'fields' covered by the institute. The concept of a 'field' was defined by the publishing patterns of the individual scientist and the whole institute. For instance, for the institute cited, the number of non-overlapping fields was calculated to be five, so that the theoretically optimal number of journals to be taken by the library was only 125.

In 1971 a survey was conducted in Edinburgh by interviewing a representative proportion of the staff of the medical school with the main purpose of obtaining an estimate of the journals that our central medical library ought to take to give reasonable satisfaction to its readership. Our survey was designed rather differently from the Aberdeen one and full details of its methodology and general results have been published¹. From the results, we were able to obtain a total figure of approximately 580 unique primary and review journals covering all the major subject areas of biomedicine, except for social medicine, public health and dentistry, which were outside the scope of our survey. I must admit that we were pleasantly surprised and relieved that the figure was not higher.

For the library of a research institute, a holding of 580 carefully chosen journals is theoretically optimal for 23 non-overlapping fields with 25 journals per field, by the Blaxters' method of analysis. In the Edinburgh medical school survey, the 580 unique journals were in fact derived almost entirely from 47 subject areas as defined by the Index Medicus List of Journals. This corresponds to an average of 12 to 13 unique journals per subject area. Many individuals in our survey had an interest in the journals of more than one subject area, and between the various medical school departments there was evidence for considerable overlap of interest. It would therefore seem not unreasonable if a 'field' in the Blaxters' sense approximates roughly in size to two average subject areas in the Index Medicus sense.

Approximate techniques inevitably have to be used to estimate the optimal journal holding for a library serving a readership of any complexity. The important point is that, though based on

different methodologies, both the Aberdeen and Edinburgh surveys produced the same conclusion: in spite of the information explosion, the optimal journal holding of a research institute or medical school library appears not to be so enormous after all, given, of course, adequate back-up facilities by a national loan service. In fairness to Edinburgh's medical school and library staff, I should add that financial restrictions have prevented our central medical library from as yet achieving the estimated optimal number of journals.

Yours faithfully,

ELIZABETH D. WHITTLE

Medical Information,
Faculty of Medicine,
Edinburgh University, Edinburgh

Cognitive Subjective

GREGORY¹ should have acknowledged sources in references to his experiments and discussion of what he calls "cognitive contours" or, as others would have it, "subjective contours". ("Subjective contours" represents a neutral description, whereas "cognitive contours" suggests the role of an intellectual process.) He acknowledges Kanizsa as the source for his Fig. 1, but does not do so for his Fig. 2c, a figure also to be found in Kanizsa (Fig. 13)². Gregory reports, in regard to one of his experiments, that the subjective contours of the Kanizsa figure can be obtained stereoscopically by proper presentation of parts to each eye. I had already reported the positive results of this experiment with a slightly modified Kanizsa figure, also showing diagrammatically the selection of parts for presentation in a stereoscope (page 296, page 405 n. 14; ref. 3). In another experiment, he points out that the sides of the subjective triangle appear curved when the edges of the sectors are not collinear, an effect which he describes as "new". I had, however, also pointed this out: "The Kanizsa diagram itself can be modified so that the subjective contours are curved. The alignment of the edges of two sectors constitute a condition for straightness of subjective contours . . . When the sectors are redrawn so that the edges are not aligned, a triangular shape with curved contours is seen" (page 404; ref. 3). Furthermore, I had noted the presence of subjective contours in the after-image of an incomplete figure (page 406 n. 22; ref. 3), as had also Gregory.

Nature regrets delay in publishing this manuscript. A part of this delay can be attributed to the transition from one Editor to another.

Announcements

Appointments

A. L. Armitage, Vice Chancellor of the University of Manchester, has been elected Chairman of the Committee of Vice Chancellors of the United Kingdom.

The following have been elected Fellows of the Royal Society: W. F. Bodmer; W. R. Boon; K. Burton; H. J. F. Cairns; R. Y. Calne; D. R. Curtis; J. F. Davidson; J. D. Dunitz; P. V. Edman; J. D. Eshelby; J. Halpern; S. W. Hawking; V. Heine; R. A. Hinde; A. E. Litherland; J. E. Lovelock; D. H. Matthews; R. E. F. Matthews; P. D. Mitchell; S. V. Perry; N. J. Petch; J. R. Philip; J. C. Polkinghorne; C. W. Rees; J. Rishbeth; R. V. Short; J. T. Stuart; R. H. S. Thompson; R. J. Vane; F. J. Vine; S. E. Words; and P. H. J. Young. D. H. Wiffen has been appointed Dean of the Faculty of Science of the University of Newcastle upon Tyne. Sir Eric Roll has been elected as Chancellor of the University of Southampton.

Awards

The Royal Geographical Society's Medals and Awards have been given to the following: C. Bonnington (Founder's Medal); G. de Q. Robin (Patron's Medal); C. A. Fisher (Victoria Medal); H. H. Lamb (Murchison Award); Captain D. W. Haslam (Back Award); M. A. J. Williams (Cuthbert Peek Award); A. R. H. Baker (Gill Memorial); Colonel J. M. Adam and I. Douglas-Hamilton (Ness Awards); and D. Bartlett and J. Bartlett (Cherry Kearton Medal and Award).

The Council of the Royal Society of Victoria has awarded Research Medals for 1973 to D. Metcalf and J. H. Willis.

W. T. Elwell of Imperial Metal Industries Ltd has been awarded the Gold Medal of the Society for Analytical Chemistry.

Missellaneous

The International Health Foundation (1 place du Port, 1204, Geneva) has announced that the theme chosen for its award scheme this year is **Oral Contraception—a 1974 critical assessment**. Applications are invited by the Council of the Royal Society (6 Carlton House Terrace, London SW1Y 5AG) for two Royal Society J. Sainsbury Research Fellowships.

Erratum

In the obituary of C. A. Coulson (*Nature*, 248, 367 (1974), who died on January 7, 1974, it was stated that he entered Trinity College, Cambridge from his local Grammar School. In fact he was educated at Clifton College, Bristol.

April 26, 1974

Twenty-one years of the double helix

WE celebrate in this issue the twenty-first anniversary of the appearance of J. D. Watson and F. H. C. Crick's short paper *A Structure for Deoxyribose Nucleic Acid* in *Nature*. A few will be offended by the equating of the twenty-first birthday with the process of coming of age when in the past few years the age of maturity has dropped to eighteen in many countries. We can do little for them. Rather more, with good cause, will say that there were earlier milestones than 1953 which marked the turning point in the fortunes of molecular biology. 1943 was a key year, with Avery's work on pneumococcus DNA at the Rockefeller Institute and Beadle and Tatum's on *Neurospora* at Stanford. As Macfarlane Burnet put it in *Genes, Dreams and Realities*, genetics was by these experiments directly implicated in biochemistry through micro-organisms. Others will also have their favourite years during which a quickening occurred, but few would carp at the Watson-Crick announcement being given pride of place as a starting point of something absolutely new and some (though perhaps not many physical scientists—either through ignorance or conviction) might go along with Medawar in calling it "the greatest achievement of science in the twentieth century".

We have tried to give a varied view of the history, present scene and prospects in molecular biology, from Chargaff's iconoclastic essay to Gurdon's report on the exciting developments in introducing macromolecules into living cells. One thing has become clear. A central contribution of the magnitude of Watson and Crick's stirs up the culture of science to a quite remarkable degree, and it is a change in the cultural climate, perhaps more even than the actual discovery itself, which breathes new life into science. Suddenly there are all sorts of new questions of history, philosophy, method and attitude to occupy the minds of the best scientists, along with the starker scientific questions and the less edifying ones of funding, organisation and priorities. Cultural revolutions in science are rare and immensely stimulating to those touched by them.

From the historical point of view an interesting aspect is the way in which the structure came to be accepted. As Brenner puts it; there was initially only a small band of believers and a positive effort had to be made to convince the biological community both of its correctness and profound relevance. This conforms to a classical view of a seminal idea's acceptance—first accepted by the few, later sweeping all before it. Contrast it with a more recent revolution in the earth sciences. There a whole army was waiting to pick up the central dogma of plate tectonics and make it their own. Was Watson-Crick the last great scientific idea that needed missionaries? It

seems unlikely. Although the number of scientists waiting for things to drop into their lap is greater than ever before, there is no sign that the community is any more sensitive to revolutionary ideas, however plainly presented.

The philosophical debates stirred up by molecular biology almost seem like a re-run of some of the issues generated by the explosive advances in physics early in this century. In the 1920s Eddington was talking in *The Nature of the Physical World* of his two tables; one a commonplace, substantial table—a "thing"; the other a scientific table, pervaded by fields of force and electric particles—an "influence". He clearly distinguishes between a "familiar world" and a "scientific world revealed by physics". The present debate in biology between reductionists and holists seems to resurrect all these old distinctions. Is a biological system more than the sum of the properties of its parts? For the philosopher, molecular biology has posed some fine questions.

Yet however stimulating molecular biology has been to historians and philosophers, the most fascinating debate has been among scientists themselves. Has the influence of molecular biology been good on biology as a whole? You will find both positive and negative answers in the articles that follow. Has molecular biology really done nothing for medical science as Burnet and many others would claim? Has it so distorted the funding of medicine that competent medical science is at risk, and has it practically destroyed certain fields of research, such as human nutrition, to which it is very difficult to attract first-rate talent? Is the pursuit of a Nobel prize through molecular biology the ultimate aim of every budding biologist? So the muttering goes, both in public and in private. These are not questions for quick answers; they are ones, however, that those outside biology should be aware of, for they represent the very central issues of science and science policy and, who knows, may crop up anywhere else at very short notice. It only needs the right sort of paper in *Nature* to start it all off.

100 years ago

DR. LYON PLAYFAIR, C.B., has given notice that, on the House of Commons going into committee on the Education Estimates, he will call attention to the deficient ministerial responsibility under which the Votes for Education, Science, and Art are administered, and will move for a Select Committee to consider how such ministerial responsibility may be better secured. We believe that Dr. Lyon Playfair's views are strictly in accordance with those of the best scientific men of the country, namely, that the only satisfactory way of dealing with the subject will be by the appointment of a Minister for Education, Science, and Art.

From *Nature*, 9, 511, April 30, 1874.

Should scientists be seen and not heard?

In recent years there has been a marked change in the way the British government is advised about scientific affairs. John Gribbin discusses this change, and the position of science in industrialised society today, in the light of the recent appointment of Dr Robert Press to coordinate the government's scientific advice.

WITH the departure of Sir Alan Cottrell to become Master of Jesus College, Cambridge, the post of Chief Scientific Adviser to the government is not to be filled from the outside world of science. Sir Alan had held his post with a grade of second secretary in the Cabinet Office, and as such ranked above almost all the scientific advisers in the various departments and ministries (the exception being Sir Hermann Bondi at the Ministry of Defence). Responsibility for coordinating scientific advice within the Cabinet Office now rests with Dr Robert Press, who as Deputy Secretary (Science and Technology) holds the same rank as most of his colleagues who are the advisers to the individual departments.

Dr Press will no doubt carry out his new role as well as anyone but the change is bound to be seen by many as a decline in the status of the post; Dr Press has also commented that he will be continuing with his previous work—chiefly concerned with nuclear affairs—so it seems that the post is not regarded as a full time occupation. And the decline of the post of Chief Scientific Adviser to the government cannot even be said to be sudden. Sir Alan himself was in many ways in a less powerful position than his predecessor, Sir Solly (now Lord) Zuckerman, and was never, for example, the Chief of the Scientific Civil Service. The latest move could well be seen as a sign that the previous situation, under Zuckerman, has now been reversed.

This is a new situation which deserves particularly close attention since so few members of the government—or indeed of either House—have any training in scientific or engineering matters. In the past, it has certainly proved possible for an all-powerful Civil Service to advise and persuade governments without taking into account the best scientific considerations; this may not happen now, but it would be much less likely to happen if there was, once again, a man in the centre with the experience and personality to take a firm grip.

No doubt the argument will be put forward from some quarters that there is no suitable man to hold such a position, and that therefore the government has been forced into the present situation. That argument carries some weight; there are always people to be found with forceful personalities and a desire to tell the government what to do about science but alas that is not sufficient qualification. What is needed is someone from the scientific community who is both well informed and respected by that community, but who has the strength of character to deal firmly with the community when necessary.

Another argument which was put forward after the announcement of Dr Press's appointment was that it is in line with the Rothschild proposals for the organisation of

civil science in Britain. Now that there are Chief Scientists in all the essential departments, so the argument runs, there is no need for anything more than a coordinator in the Cabinet Office. That argument, however, seems to rest on a singular interpretation of the Rothschild report.

But outside the immediate issue, the question of the place of science in society is even more disturbing. At present there is an urgent and growing need for science to be used constructively by governments; there is a strong likelihood that the present situation will be no different in practice from the situation with Sir Alan Cottrell as Chief Scientific Adviser, but there is very little chance of changes being made in the required direction. In part, to be sure, the need is for a cleaning up of the mess made by the misuse of science in the past. That, however, makes the present need for correct use of science no less urgent. Yet there seems to be a great public apathy about science, at least in the industrialised nations of the world.

There is a need to provide scientific education in the broadest sense, to get the scientific message across to the general public and to the rank and file Members of Parliament, if not to the government itself. There is at present a bizarre situation in which there is concern at all those levels that the few millions of pounds worth of aid which Britain is providing for drought-stricken regions of Africa may be inadequate, and yet there is no move to provide a few tens of thousands of pounds for research into the causes of such droughts (see *Nature*, 248, 466; 1974). Seldom can there have been a more straightforward example of prevention (if possible at all) being better than cure; there must be many other cases where foresight and the correct application of current scientific knowledge would produce enormous benefits.

Part of the blame for the confusion and apathy in the public mind must be laid at the door of the Press. There were only a few brief paragraphs in the British national papers commenting on the new situation in the Cabinet Office, and at least one responsible newspaper carried an incorrect and misleading account which largely obscured the real significance of the situation. Members of both the Royal Society and the Institution of Mechanical Engineers have recently expressed concern about the failure of scientists to get their message across. If this concern is to be turned into something more constructive, those august bodies might well be advised to investigate ways of encouraging the spread of the scientific message through the journalistic medium.

It is, however, less easy to see an obvious immediate solution to the problem of providing the right kind of scientific advice to the government. If there are serious objections to placing too much scientific authority in the hands of one man, there is one obvious alternative which has been touted, and that is to expand the role and responsibilities of the Advisory Board for the Research Councils (ABRC). This has superficial appeal. Sir Alan was, of course, represented on the ABRC and Dr Press will be too. So the channel of communication is there and might be strengthened into something more without great difficulty.

But government by committee is always undesirable and advice by committee hardly less so. Since the role of Chief Scientific Adviser, which has now disappeared, was largely one of assessing priorities, it is difficult to see how the work could be delegated and shared out. Someone must see everything in order to assess the priorities, and in that case the committee is redundant. There seems no easy solution; but the present situation is far from satisfactory. At a time when the government is faced with questions of greater scientific complexity and urgency than ever before in peacetime it is disturbing to find the scientific community asking: Where is the voice of science and engineering in government?; it is perhaps even more disturbing to guess the likely public response to such a question: We don't know and we don't care.

international news

EACH year in the United States between 100 and 1,000 people undergo a highly controversial surgical operation which consists of the destruction of tiny portions of their brain. Popularly known as psychosurgery and designed to alter behaviour, the operation has become the centre of a bitter public debate over its legal and ethical implications, as a result of which the federal government is cautiously moving toward adopting a set of recommendations and regulations for controlling the technique.

The latest move is that staff members of the National Institute of Mental Health (NIMH), the agency which funds the bulk of government-supported psychiatric research, have sent a report to the Assistant Secretary for Health listing a set of recommendations for consideration as official government policy. As set out in a memorandum signed by the Director of the NIMH, Bertram S. Brown, and prepared with the help of a panel of distinguished outside experts, the suggested regulations would outlaw some of the more controversial applications of psychosurgery—its use on children, prisoners and incarcerated mental patients—but they stop well short of calling for a complete ban on the technique.

The controversy generated by psychosurgery has stemmed largely from charges that the technique is nothing more than a dressed-up version of lobotomy, the surgical operation popularised in the 1950s which has since been discredited, leaving thousands of people with impaired mental function. Supporters of the technique argue, however, that it is an acceptable form of therapy for severe behaviour disorders which have not responded to more conventional psychiatric treatment.

Unfortunately, the debate has not been helped by the fact that many of the psychosurgery operations carried out in the United States have been performed with hopelessly inadequate follow-up procedures, so that it is difficult to form any conclusions about the efficacy of the technique. As the NIMH memorandum puts it, "inadequacy of pre- and post-operative behavioral and psychological testing, lack of long term follow-up of patients, and general inadequacies of clinical and behavioral reporting characterise much of the published literature."

On the other hand, critics of psychosurgery have managed to cite examples in which psychosurgery operations are

Rules for psychosurgery

Colin Norman, Washington

Brown: signed memo

alleged to have resulted in severe damage to the intellect of patients and they have brought up passionate arguments to suggest that the operation has been used to alter the behaviour of emotionally disturbed children for the convenience of their parents.

One incontrovertible aspect of the operation is that its effects are irreversible because it involves the destruction of brain tissue which is not regenerated. In that case, why did the NIMH not recommend at least a moratorium on the technique until some of the more serious charges that have been levelled against the operation are cleared up?

The memorandum gives three reasons. First, such a recommendation "would constitute an unprecedented federal prescription of the parameters of permissible and impermissible surgery for the medical profession". (The NIMH staff did not feel themselves to be under such a constraint in recommending that the technique should not be used on children, prisoners and involuntarily detained mental patients, however.) Second, since there is no precise definition of psychosurgery, the memorandum suggests that a moratorium would be rendered ineffective because the operation could be performed under the guise of treatment for epilepsy and other neurological disorders. And third, the proposed regulations would at least amount to a partial moratorium on the most controversial forms of psychosurgery.

In short, the memorandum suggests regulations "with the intent of providing the maximum possible protection for potential psychosurgery candidates without unduly inhibiting practice for those cases which, judged by our present standards and knowledge, appear to require psychosurgery for relief of extreme mental illness or behaviour disorders". So the NIMH at least accepts some of the arguments for psychosurgery.

Perhaps the most important recommendation is that psychosurgery should be regarded as strictly experimental and not a form of therapy. Such a designation would slap a number of controls on use of the technique, such as the development of comprehensive research protocols to ensure that maximum scientific value is gained from each operation. It would also mean that psychosurgery should only be carried out in hospitals attached to universities and "every effort must be made to ensure that all reasonable alternative therapies . . . are attempted to an adequate extent before resorting to psychosurgery".

The NIMH is also recommending that a widespread effort be initiated by the federal government to obtain more precise information about the results of psychosurgery operations performed in the past, the idea being that such information can later be used as a basis for more permanent guidelines governing the future use of the technique.

The memorandum is now being reviewed by Charles C. Edwards, Assistant Secretary for Health, but whatever finally becomes of it, the federal government can only directly control those psychosurgery operations performed with government money. The control of such operations carried out in hospitals and universities independently of federal funds lies outside the direct jurisdiction of the Department of Health, Education and Welfare.

But at least the widespread public controversy which has been generated in the past couple of years, chiefly through a court case which halted the use of psychosurgery on an involuntarily detained mental patient last year and a bruising public inquiry conducted by Senator Edward M. Kennedy's health subcommittee, should make it more difficult for the operation to be carried out with inadequate controls.

Pure science and the energy problem

Miranda Robertson, Chicago

MUCH the largest contribution of the Argonne National Laboratory to the problem of developing a new energy technology is its experimental liquid-metal fast-breeder reactor, and nuclear energy will continue to account for nearly half the total research expenditure of the laboratory. But recent shifts in the emphasis of federal funding are reflected in the expansion of research on a wide range of alternative and accessory approaches to the problem. At the same time, the laboratory (which is controlled by the United States Atomic Energy Commission) is beginning to feel the effects of a general movement to involve basic scientists in applied research, as interpreted by its new director, Dr Robert G. Sachs, now at the end of his first year at Argonne. A vigorous proponent of the view that fundamental scientists represent a national resource to be supported for reasons of enlightened self-interest, he believes that the time has now come to draw on that resource for the answers to a national problem. He also believes that a degree of mission-orientation need detract from nobody's fundamental research pursuits. The effects of both federal and local policy are nowhere better illustrated than in the birth of a new research project on solar energy in which Argonne personnel are collaborating with Dr Roland Winston from the Enrico Fermi Institute at the University of Chicago, where Dr Sachs holds a chair.

The outcome of this joint enterprise could be the development of a much more efficient solar energy collector than could be envisaged with known techniques; but it began as pure research on high energy physics. The problem to which the Winston advice was originally addressed was that of collecting Cerenkov radiation for the detection of rare electrons resulting from the β decay of a λ particle. The essential feature of the device was that it should not miss any radiation from the reaction.

Eventually, by departing from the principles of imaging optics, which limit the possible degree of concentration of the intensity of solar radiation to a factor of three, he arrived at an ideal light collector in the form of a cylindrical paraboloid with a theoretical maximum degree of concentration of ten times. The device represents a new principle as far as modern physics is concerned, although Professor Ricardo Levi Setti, a colleague of Winston's in the physics department, has discovered identical

shapes in drawings of Descartes and in the individual eye-cups of the horse-shoe crab. What Levi Setti also recognised, however, was that as well as having an interesting past the device has an important potential future as a concentrator of solar energy.

The problem of concentrating sunlight is only one of the obstacles to the utilisation of solar power to generate electricity, but it is one of the principal stumbling blocks in using it to heat and cool individual homes. The exploitation of solar energy for this purpose is already feasible and as a result of vigorous advocacy in the past year there has been an increase in the allocation of research funds as well as the institution of tax incentives for the conversion of buildings from conventional heating and cooling systems. But although solar heating is comfortably within the capacity of existing types of collector, cooling, which is much less efficient and in some areas in the summer stretches electricity generation to the point of overload, is more marginal. The increased concentration factor of the Winston light collector may overcome the difficulty. Its other

important advantage is that it can be designed so as to obviate the need for tracking the movement of the Sun across the sky, thus greatly reducing the complexity and the energy cost of the system. Winston's first model for a roof unit consists of a series of collectors shaped as paraboloid troughs which can be aligned with the Sun's trajectory so as to collect light for an average of eight hours a day.

The promise of the device has been endorsed by the allocation, in mid-fiscal year, of some \$200,000 from the United States National Science Foundation and the Atomic Energy Commission for feasibility studies. Winston and his collaborators at the Argonne are now working on such questions as how much light is actually collected by an ideal light collector made from nonideal materials and functioning under nonideal conditions. One of the problems being tackled is the development of what amounts to a new meteorological dictionary: for example, 'overcast' might mean something very different in terms of collectable solar radiation than it means in the week-end weather report.

Solar energy in suspense *Colin Norman, Washington*

Although almost everybody agrees that solar energy is a splendid idea whose time has come, a bill designed to hasten commercial application of solar heating and cooling technology has fallen foul of a jurisdictional squabble in the United States Senate and its passage has been delayed for several months while no less than five different committees have staked their claims on the legislation.

Passed by the House of Representatives in mid-February, the bill is designed to provide federal support for the development and testing of solar heating and cooling devices in private homes, office buildings, factories, schools and various other buildings. The idea is that the National Aeronautics and Space Administration (NASA) would be given some money to let contracts with industry for development and mass production of solar heating and cooling units, while the Department of Housing and Urban Development (HUD) would be responsible for carrying out prototype demonstrations to see how well the units perform in everyday use.

After being approved by the House—by a margin of 248 votes to two—the bill was referred to the Senate Committee on Aeronautical and Space Sciences which made a few amendments and passed it on March 13. In the meantime, how-

ever, four other senate committees—Commerce, Labour, Interior and Banking, and Housing and Urban Affairs—all argued that the bill should come under their purview, so it was then referred to each of them separately.

The irony is that once the various committees have finished guarding their legislative jurisdictions, the bill which finally emerges will probably be similar to the version which was passed by the House, except for one important detail. The House bill would have provided \$50 million for the programme over the next five years, but the Senate Space Committee has suggested that NASA and HUD should each get \$5 million next year to carry out their parts of the enterprise and funding for future years should be left open for now.

As for the administration's attitude to the bill, Dr H. Guyford Stever, Director of the National Science Foundation and Science Adviser to the White House, has argued that although the demonstration scheme is a good idea, it is a little premature. The Administration has already proposed that \$50 million should be spent next year on solar energy research, and Stever reckons that it would be wise to wait until some of this effort bears fruit before rushing into a federally sponsored application programme.

The Strangelove scenario

Colin Norman, Washington

BY THE year 2000 there could be enough plutonium and enriched uranium flowing through the nuclear power industry in the United States to manufacture about 250,000 crude atomic bombs. The sheer magnitude alone is sufficient to conjure up Dr Strangelove scenarios of nuclear theft. But is it really feasible for a few terrorists to make off with several kilograms of the stuff, fashion it into a weapon and hold a city to ransom—or even to create a nuclear holocaust in the Middle East?

According to a book-length report prepared for the Ford Foundation's Energy Policy Project, the short answer is yes, unless the Atomic Energy Commission (AEC) improves its control over weapons-grade nuclear material and unless officials in the energy industry, many of whom are "only vaguely aware of the problem", are made to take effective (and costly) steps to safeguard the potential nuclear weapons that they handle every day. (*Nuclear theft: Risks and Safeguards*. Mason Willrich and Theodore B. Taylor. Ballinger Publishing Company, Cambridge, Massachusetts, 1974).

The study's conclusions are likely to provide some powerful ammunition to nuclear critics in the United States who have recently seized on the issue of weapons' proliferation as yet another club with which to beat the AEC and the nuclear industry, particularly with respect to plans to build a string of plutonium-producing fast-breeder reactors around the country. But they are unlikely to shake the Administration's unswerving commitment to nuclear power, and spokesmen for the AEC have already rebutted the report's chief conclusion by arguing that existing safeguards are sufficiently stringent to ensure adequate protection of public safety and national security.

Be that as it may, the study provides strong evidence to suggest that a crude atomic bomb could be manufactured in a clandestine laboratory by a few people with a relatively modest amount of nuclear know-how, about 10 kg of plutonium oxide, a substantial amount of chemical high explosive and "materials and equipment that could be purchased at a hardware store and from commercial suppliers of scientific equipment for student laboratories". A bomb made of highly enriched uranium (containing more than 90% uranium-234) or uranium-233 would be assembled a little differently from a plutonium bomb, but it could also be made relatively easily with a supply of

15 kg or more of fissionable material.

Although that may sound like fantasy to some weapons designers, the authors of the study point out that few experts have asked themselves the question: "What is the easiest way I can think of to make a fission bomb, given enough fission-explosive material to assemble more than one normal density critical mass?" And they cite an article in the *Encyclopedia Americana*, written by Dr John S. Foster, former Director of Defense Research and Engineering and an expert on nuclear weapons' technology, who states that "the only difficult part of making a fission bomb of some sort is the preparation of a supply of fissionable material of adequate purity: the design of the bomb itself is relatively easy".

Moreover, the two authors of the report have some impressive credentials in the nuclear weapons field to back up their analyses. One of them, Mason Willrich, now Professor of Law at the University of Virginia, was General Counsel of the United States Arms Control and Disarmament Agency, and the other, Theodore B. Taylor, worked on nuclear weapons design at the Los Alamos Scientific Laboratory and was Deputy Director of the Pentagon's Defense Atomic Support Agency. Taylor emerged a few years ago as the chief critic of the AEC's nuclear safeguards and has become a rather prominent thorn in the agency's flesh.

It is not difficult to predict the consequences if a crude nuclear weapon does end up in the hands of a terrorist organisation. The authors of the study point out, for example, that even a "small" nuclear device exploded underneath a large city skyscraper might kill as many as 50,000 people: a comparable explosion in the centre of a football stadium could lethally irradiate about 100,000. As for the injection of nuclear weapons into the Middle East, the political fallout would be devastating.

So, assuming the validity of the theory that a crude atomic weapon could be manufactured relatively easily, the crucial consideration is how easily can fissionable material be stolen from the nuclear power industry? Willrich and Taylor argue that although there is little risk at present that a terrorist could make off with a few critical masses of explosive material, the burgeoning growth of nuclear energy and the changing characteristics of power plants will greatly increase the chance of illicit diversion of the stuff. They suggest that unless the AEC adopts an improved safeguards system now, it may soon be too late.

The most vulnerable part of the fuel cycle to terrorist activities is the transportation of weapons-grade materials

between facilities, according to the study, and the greatest chances for diversion will come when large quantities of plutonium (in particular) are moved around the country. At present, the movement of plutonium is not substantial, but in the next few years it is likely to grow significantly.

Nuclear energy is now produced almost entirely by light water reactors which are fuelled with uranium, only slightly enriched with the uranium-235 isotope. The fuel itself is thus of no use as weapons material, but the reactors do produce plutonium, which is separated out from the spent fuel rods and stored. According to Willrich and Taylor, this plutonium is now adequately protected against theft, but in the late 1970s it will be recycled for use as fuel in light water reactors, which means that it will be transported from the storage facilities to the power plants. The inherent risk of theft will then be "considerably greater".

In the 1980s and 1990s, when the liquid-metal fast-breeder reactor (LMFBR) is likely to be introduced commercially, the availability of weapons-grade nuclear material will again increase dramatically. The LMFBR produces large quantities of plutonium, which will be extracted from the spent fuel rods and recycled for use as reactor fuel. Since the AEC has forecast that by the year 2000 breeder reactors could be generating up to 750,000 MW of electricity, Willrich and Taylor calculate that if all goes according to plan, about 3,000 truckloads of plutonium oxide would be shipped to LMFBR and light water reactor fuel fabrication plants every year.

And these figures are given added significance if the possibility that a small amount, insufficient to make a bomb but enough to make a radiological weapon, is taken into account. Since plutonium is highly toxic, and easily dispersed in the form of tiny airborne particles, it would be possible to pose a severe risk to a large population with only about 100 grams.

Given the possibility of such dire consequences resulting from the theft of comparatively tiny amounts of fissionable material, is the AEC making sure that the material is properly protected? Willrich and Taylor think not. For one thing, they point out that there are no specific requirements for the physical protection of less than 2 kilograms of plutonium, although that would be more than enough for a radiological weapon. And for another, they suggest that regulations governing communication with vehicles transporting fissionable material are not particularly effective.

But a safeguard system can be developed to keep the risk of theft to "very low levels". First, the study recom-

mends that the AEC should design a system of safeguards for each nuclear fuel cycle, based on the best technology available, and the agency should also consider the possibility of establishing a special federal security service whose sole job would be to protect nuclear material at fixed sites and during transit. Willrich and Taylor also suggested that careful consideration should be given to locating fuel reprocessing and fabrication plants side by side, to cut down the transportation of nuclear fuels between facilities. Finally, they suggest that the United States government should initiate discussions with other countries which have substantial nuclear power programmes in an effort

to develop a common policy towards international safeguards against nuclear theft anywhere in the world. The AEC's reaction is that its safeguards are more effective than Willrich and Taylor suggest.

But the credibility of the agency's safeguards received a severe blow last year when the General Accounting Office (GAO), a watchdog agency of the United States Congress, published the results of an inspection of three plants which handle strategically significant quantities of fissionable material. The GAO found evidence of laxity such as gaping holes in perimeter fences, inadequate burglar alarms and vulnerable storage facilities.

The TU-144: traumatic crash

Russians in the air *from our Soviet Correspondent*

AVIATION has always been considered a 'prestige' achievement in the Soviet Union, from the early 1920s when the propagandists of atheism solemnly argued that "There is no God for our brave airmen have failed to find him," through the spectacular air-lift, in March-April 1934, which evacuated 104 icewrecked survivors (including the inevitable newborn infant) from the polar research ship 'Semen Chelyuskin', through the 1945 anniversary celebrations of the Academy of Sciences when Joukowski received almost as much acclaim as Stalin up to the present day and the maiden flight of the TU-154 jet airliner from Moscow to Helsinki on April 9. The highly publicised crash of the TU-144 at last year's Paris air show, therefore, must have been a traumatic experience, not only for the Soviet aviation industry but for all concerned in the mass media.

According to the tenets of Socialist Realism, the press and other media, including the fine arts, should strive to present, not the transient defects of the world as it is but a sort of Platonic ideal of what it one day will be. The aftermath of the TU-144 disaster has, therefore, resulted in an even greater than usual press coverage of the positive aspects of aviation.

Nevertheless, since the Paris disaster there seems to have been a change in Soviet aviation policy, as reflected in

the press coverage. Whereas in February 1973, an *Izvestiya* article could state that the decision of PanAm and TWA not to take up options on Concorde was dictated not by commercial but by political motivation (since the United States "have nothing to compete with Concorde or the TU-144"), now the stress is all on co-operation with the United States. In January, a five-year cooperation agreement was signed between Lockheed and the USSR State Committee for Science and Technology, providing for the joint development of civil aircraft construction, navigation systems and aviation electronics. The inauguration of the direct Moscow-Washington air route was hailed by *Pravda* as "a major contribution to the further development in the extension of mutually advantageous economic cooperation of two great powers". For the moment, the negative aspects of competition seem to be minimised.

And yet since Concorde (in conjunction with the TU-144) has always been presented in the Soviet press as Europe's answer to the American aviation "threat", it is perhaps not without significance that, according to the Novosti agency, a factory at Kramatorsk (Ukrainian SSR) has begun work on a 60,000-tonne hydraulic press for the manufacture of large scale components of Concorde supersonic airliners.

OECD probing in Australia

Peter Pockley, Sydney

A TEAM of three examiners from the Organisation for Economic Co-operation and Development (OECD) is now in Australia for the first independent examination of the nation's organisation, funding and policies for science and technology. The team is led by Dr Alexander King, the OECD's Director-General for Scientific Affairs, who is an old hand at OECD science policy surveys; this will be his last one before retirement. Other members of the panel are Dr Freidrich Schneider of West Germany and Dr J. Wautrequin of Belgium.

Australia joined two dozen other nations as a member of the OECD just over two years ago and the current survey of Australia is the nation's first major examination under the organisation's critical microscope. The results should be interesting, not only for scientists but in a wider sphere as a measure of the nation's maturity in taking authoritative, international criticism on the chin and of the government's capacity for instigating sensible, perhaps radical, reforms which have not originated from internal, political pressures.

That such reforms may be recommended seems likely from the widely circulated comments of the OECD panel before its arrival in Australia at the end of March. Its comments were written in response to the background document prepared for the OECD by the Department of Science; they spoke of a good deal of thought being needed about weaknesses in the system, lack of balance and the need to develop in new directions. The OECD also noted the heavy concentration on government-run or government-sponsored science.

In a closely packed series of meetings, the team is now finding out for itself just how decisions of priority are made (or more to the point, how they are not made) in Australian science. Given the level of expenditure on research and development in Australia (now running at about \$A450 million a year), it may seem surprising that no similar survey has previously been conducted within Australia. Even now, there is no academic unit or independent institute in Australia which is professionally interested in the study of science policy on anything more than a part-time basis. The School of Sociology at the University of New South Wales is the nearest approximation to such a unit; senior staff are making a habit of spending sabbatical years in Britain at the Science Policy Research Unit at the University of Sussex.

Another continuing deficiency which the OECD team has already picked up, is the small amount of information in general circulation about the achievements and quality of scientific research *per se*. The background document presented by the government to the OECD confirmed this by dealing exclusively with the organisation of science in the country, almost as if the products of the research effort were hardly worth mentioning. The OECD examiners are hardly likely to be diverted from their stated objective of assessing the value of work done, as measured through accepted international criteria of scientific interest and merit. Their report should therefore prove doubly informative to Australians in positions of power who are ignorant of the very real achievements of science, notably outside the fairly well publicised government sector, such as the Commonwealth Scientific and Industrial Research Organisation (CSIRO).

In the week before the OECD team arrived in Australia, the Minister for Science, Mr Bill Morrison tabled a Green Paper in the Parliament entitled *Towards an Australian Science Council*. Presented as a discussion paper rather than a blueprint, this document spells out the government's long-drawn-out uncertainty about the terms of reference and functions of the council, which they first proposed in their Labour Party Platform before the elections of December 1972.

In his speech about the green paper, Mr Morrison opened with a statement about "public disenchantment (which) has risen with the part played by science and technology in developments of dubious value to mankind". While this point can obviously not be ignored, the prominence given to it by the minister does cast doubts on his determination to bat vigorously in Cabinet on behalf of an expanding budget for science. All present indications are that funds for science will remain largely stagnant in relation to many other rapidly expanding areas of government spending in the country.

In this respect it is possible that the OECD examination is being quietly considered as providing justifications for different ways of slicing up the same financial cake. But, the OECD has made many acute observations in other countries, and it is equally possible that it will shake the assumptions of the Australian scientific bureaucracy and its political masters to the core.

Unfortunately, though, the effect of the report may be dulled within Australia by the present plan to present and discuss the report at the OECD headquarters in Paris, rather than in Australia.

European Earth scientists disunite

Peter J. Smith

ONE of the benefits often claimed for the recent revolution in the geological sciences is that it has finally succeeded in uniting solid-earth scientists of all disciplines. The new global tectonics, the argument goes, has provided a conceptual framework which enables almost every student of the Earth to find a place in a common enterprise. In the purely academic sense there may be some truth in it; but if recent events in Europe are anything to go by, interaction between geologists and geophysicists remains firmly bound between the covers of the learned journals.

The possibility of a serious breakdown in communication between the two groups first became apparent late last year when the General Secretary of the European Geophysical Society (EGS) discovered more or less accidentally that the Geological Society of London and the University of Reading were jointly planning a "meeting of European geological societies". For some time the precise purpose of the meeting remained unclear to the geophysicists, although it was widely believed that in addition to scientific sessions there would be an evaluation of the need and/or desire for the formation of a Geological Society of Europe (GSE). (One of the meeting's chief organisers said that no such thing was intended, although when the EGS General Secretary later relayed this information in good faith to a scientific conference in Peru it was flatly contradicted by another of the meeting's organisers).

Now that it has been formally announced that the meeting will take place at the University of Reading in September 1975, it is possible to see that its official object is "to provide an opportunity for members of European earth science societies to discuss (1) common scientific, economic and organisational problems, and (2) ways of promoting closer cooperation in future". The vagueness of this statement and the continued inability of the EGS General Secretary to get any more specific information from the sponsors of the Reading meeting have apparently upset many members of the EGS Council who feel that, whatever is going on, some prior consultation would have been both desirable and tactful. They are also concerned about the scientific theme of the proposed meeting, which is "Europe from crust to core". There being no such thing as the geology of the core, it is evident that the Reading meeting must incorporate some element of geophysics—

a subject which is already catered for on a Europe-wide basis by the EGS itself.

In spite of previous contradictory statements it seems likely that the possibility of a GSE will be discussed at Reading in some form. What particularly puzzles the EGS Council, therefore, is that the sponsors of the meeting apparently see no merit in drawing on the experience of the founders of the EGS and the council itself. After all, for several years prior to the formation of the EGS the problems involved in the cooperation of European earth scientists were discussed in great detail.

Given that European cooperation is desirable, the basic question as the geophysicists see it is whether there should be a single European Earth Science Society or whether geologists, geophysicists, geochemists and other such groups should go their own separate ways. Both arguments and individuals within the EGS seem to be about equally divided on this point. It is widely agreed that of overriding importance is the desirability of greater communication between earth scientists of all disciplines, a need increasingly dictated in any case by the way the subject itself is developing. On the other hand, if that implies the need for a single organisation, there are likely to be severe practical problems.

For one thing, geologists greatly outnumber the members of the smaller disciplines, and so there is a real danger that in an all-embracing body the latter group would become submerged—a thought which was very much in the minds of the founders of the EGS when the question of scope first arose. Second, there is the problem of logistics. More than 600 scientists attended the first EGS meeting held last year in Zurich; several thousands could be expected at a meeting of a combined European Earth Science Society. Quite apart from the fact that many people have expressed abhorrence at the mere idea of such a large gathering and that others have doubted the possibility of true communication in such conditions, suitable venues for very large meetings in Europe are surprisingly scarce. Moreover, one of the prime aims of the EGS in particular is to attract relatively impoverished students and research workers at the beginning of their careers; and this cannot be managed without cheap accommodation for conference participants. Finally, there is the point that there are still many geologists and geophysicists working in fields in which, rightly or wrongly, there is still little recognised need for cooperation with other branches of the Earth sciences.

The EGS believes that if a single European organisation with a single

annual meeting is to be ruled out, the best solution would involve individual bodies holding separate meetings at the same location but in successive weeks. In this way scientists could attend one, or the other, or both, of the meetings as they wish without doubling travel costs. The fact remains, however, that no satisfactory solution will emerge at all and chaos is likely to result unless geologists and geophysicists talk to each other. The EGS Council has now written to the organisers of the Reading meeting expressing concern at the meeting's scientific theme and formally requesting consultation on matters of mutual interest.

New union in Canada

from a Correspondent

ON February 22, 1974, the first meeting of a newly formed Canadian Geophysical Union (CGU) was held in Ottawa; it was chaired by the union's first president, Professor J. Tuzo Wilson of the University of Toronto. Canadian geophysics has been well served in the past by the National Research Council of Canada (NRCC) through its system of associate committees and sub-committees. Established in 1945 (also under the chairmanship of Professor Wilson) and active ever since, the Associate Committee on Geodesy and Geophysics has been the main co-ordinating body, the clearing house, for scientific and technical information, and the benevolent patron of most geophysical research in Canada. The main activities of the Associate Committee were semiannual meetings at which the progress of various research projects were discussed and early scientific results announced, and the publication of an annual *Geophysical Bulletin* containing the reports of activities of all important centres of geophysical research in Canada. Twenty-five published volumes of this bulletin provide an opportunity for all geophysicists to find out about programmes of research outside their own field. But the NRCC itself is being reorganised and as part of this process geophysicists have been nudged out of their warm and cosy nest.

The programme of the inaugural meeting consisted of two parts: a presentation of "Frontiers of Science" lectures and a panel discussion on the future of geoscience in Canada. The first part suggested that the progress of geophysical research is healthy; the second part suggested that the assembled membership did not anticipate any serious problems ahead. Surprisingly, there was no mention of shortages of research funds although there were polite suggestions that more effort

should be devoted to this or that project (theoretical geophysics, geodynamics of the Earth's interior, exploration geophysics research and so on). The question of whether the participation of Canadian geophysicists in international science is at an adequate level was discussed but no conclusions were reached. Also unanswered was the question: "What are the government organisations responsible for regional geophysical surveys going to do when these regional surveys have been completed?"

The CGU will be the national body adhering to the International Union of Geodesy and Geophysics (IUGG). Its stature at the international level will be assured by the support it has from prominent Canadian geophysicists. The strength of its voice in national affairs will depend on the membership it can attract and there will be competition with a number of specialised societies loosely federated in the Canadian Geoscience Council. Because of the size and the geographical situation of the Canadian land mass and the adjacent offshore areas, geophysicists working there have always taken their responsibilities to international science seriously. On the continental scale these responsibilities have included standardised seismological networks, regional gravity maps, surveys of the magnetic pole and research on Aurora. On the scale of global geophysics the new union has an important role to play and the international scientific community will watch its growth with interest.

Medical research in the dock

A Boston grand jury has set the stage for two separate court battles, one of which holds important implications for medical research, and the other involves a legal challenge to a key aspect of the historic decision on abortion which was handed down last year by the US Supreme Court.

In the first case, four medical researchers have been accused by the Grand Jury of violating an obscure Massachusetts law in connection with a research project they carried out at Boston City Hospital in 1971 and 1972. If the accusation stands up in court, it could put an end to all research on foetal tissue in Massachusetts.

The research involved giving antibiotics to 33 women scheduled to undergo therapeutic abortions, in an attempt to determine which of the drugs was more effective in crossing the placenta. The objective was to find an antibiotic to use instead of penicillin for curing foetal infections. After the abortions were performed, the dead foetuses were

analysed for signs of drug residues.

The doctors have been charged with illegal dissection of non-living tissue under a 19th century Massachusetts law designed to prevent graverobbing. Medical researchers in the Boston area have been quick to point out that research on dead foetal tissue has played an important part in the development of vaccines and that foetal tissue is often vital for all sorts of medical investigations. In fact, two Harvard scientists, Dr Thomas Weller and Dr John Enders, won the Nobel Prize in 1954 for growing polio virus in cells cultured from foetal tissue.

If the prosecution is successful, the ban on such research would extend only to Massachusetts, but since there is a huge medical research complex in the Boston area, its effect would be very keenly felt. In the meantime, the Massachusetts State Legislature is considering a bill which would impose a flat ban on research involving aborted foetuses, so even if the ancient graverobbing law proves to be ineffective, Boston scientists are still in danger of being saddled with legal prohibitions on their work.

The second case involves an indictment against Dr Keith Edelin, Chief Resident in Obstetrics and Gynaecology at Boston City Hospital, who has been accused by the same Grand Jury of manslaughter in connection with a legal therapeutic abortion which he performed last October. He has been charged with killing a foetus, reported to be between 16 and 24 weeks old, which the prosecutor's office maintains was a viable human being.

When the case is eventually brought to court, the central issue will revolve around the responsibility of a doctor to do all in his power to keep an aborted foetus alive. This is an issue which was left rather murky by the Supreme Court, which argued that the state has a right to protect the life of an unborn child only when it is 'potentially able to live outside the mother's womb, albeit with artificial aid'. This usually occurs, the court said, at 'about seven months'.

The Supreme Court decision overturned a Massachusetts anti-abortion law, and Edelin's indictment has been viewed by some observers as an attempt to challenge the court's decision and to define more rigidly the concept of viability. In Catholic Boston, there is a very potent anti-abortion lobby.

Edelin's colleagues at Boston City Hospital have published a statement suggesting, in fact, that he may be a scapegoat for the anti-abortion forces, and they have predicted that he will be cleared when the facts are known. In any case, the court case is going to be closely watched throughout the country.

news and views

Water, myth and magnetism

IN these days of the Geller effect, the perhaps magnificently lost causes of quarks and gravity waves and the great international *Bockschiessen* over polywater, it would be a pity to lose sight of the fact that, at any one time, there are probably a handful of minor absurdities lurking on the fringes of orthodox physics which, although lacking some of the sensational character of the examples mentioned, seem nonetheless worth bringing into the open.

One such case recently drew me into previously unsuspected backwaters of the physicochemical literature to a number of articles which, though preposterous in many respects, seemed to leave enough important questions unanswered to be worth describing. It concerns the alleged possibility of producing mysterious changes in the physical properties of water by the application of relatively weak magnetic fields—permanent changes or transient ones depending which of several authors one is inclined to believe.

The subject of the magnetism of water surfaced briefly in the mainstream literature about two years ago with a perfectly unsensational paper by Quickenden, Betts, Cole and Noble of the University of Queensland (*J. phys. Chem.*, **75**, 2830; 1971) who carried out a meticulous null experiment showing, to nobody's great surprise, that no detectable changes in *pH* can be found in magnetically treated water, none being in any case remotely conceivable in terms of any electronic model for the water molecule. It is in the more obscure papers which inspired Quickenden *et al.* to undertake such a seemingly futile measurement that the case becomes curiously and curiously.

Their immediate stimulus was a paper by Joshi and Kamat (*J. Indian chem. Soc.*, **43**, 620; 1966) claiming to have obtained not only changes in *pH* of about half a unit in CO_2 -equilibrated water but—for good measure—distinct, irreversible changes in surface tension and dielectric constant as well, all with fields little stronger than that of a permanent bar magnet. At this point the armchair theorist (or rather one perched high on a Patent Office stool) finds that the subject extends back from familiar territory into the somewhat alien world of hydrology, boiler-feed management and the suppression of incrustations in the conduits of spas and watering places. It seems that, for a considerable time, boiler engineers in many parts of the world have been passing their feed water through quite mild magnetic fields and obtaining a sensational reduction in the deposition or, more correctly, the adhesion of scale as a result. A wave of testimony to this passed through the relevant literature about ten years ago, with rapturous accounts originating as far apart as the Works for Heavy Machinery Construction in Alma Ata (Bitny *et al.*, *Bezop. Truda v Prom.*, **3**, 22; 1959) and the Belgian Institute for Corrosion Research CEBELCOR in Brussels. Some accounts claim that passage of feed water through the field of a small bar magnet can actually lead to removal of scale already deposited, patents have been taken out and there is mention of a figure of 50,000 successful installations of the "CEPI" device, embodying a small permanent magnet in the inlet.

When I took this up with one particularly wise and ex-

perienced physical chemist, his reaction was that this was nothing compared with some of the almost magical practices resorted to by boiler engineers. For instance, had I heard of the use of glass globes containing helium and a little mercury tethered in the water supply and said to be almost as effective as the magnetic system? I had not but some further research turned this up too, in an article by Friedel (*Chem. Ztg.*, **84**, 539; 1960) who attempts to explain the electrochemistry of both this, the "Tonisator" as it is called, and the CEPI method. Friedel's explanations, invoking Geissler discharges and a permanent magnetically induced strain in the bond angles of the H_2O^+ ion, are far fetched by any account, though this might be held to be of little concern to the improbable 50,000 maintenance men the world over, released by the CEPI device from the unpleasant task of periodic chipping out with a descaling hammer.

But, if one must single out the most remarkable paper of all on water magnetism, it must surely be that of Bruns, Klassen and Kon'shina of the A. A. Skochinskii Mining Institute in Moscow (*Colloid J. USSR*, **28**, 129; 1966), likewise backed up by another whole sublitterature from Russian specialist sources. Bruns and colleagues go further than the other work cited in two respects. They claim that the optical absorption of water can be altered up to some 30% by quite moderate magnetic fields, the treated water regaining its normal state with a time constant of some hours, and further that the effect is periodic in the applied magnetic field strength. (Here, however, it must be solemnly recorded that some of the 'periodic' data presented is drawn with two maxima and minima spaced among only five data points.) The explanation proposed is that there is a 'resonance' interaction with the vibratory motion of groups of associated water molecules under the influence of the field . . .

After all this it seems almost hubristic to suggest that, if magnetic fields can really interfere with the *pH* or any other electrochemical property of water significantly, it might be a very painful and hazardous business putting one's finger between the poles of a strong electromagnet. (True that blood is effectively buffered, but why should the buffer *pKs* be any more immune to magnetic interactions?) Of course biological effects of magnetic fields are known but they are weak and elusive and, on the whole, poorly documented. Mice show no particular ill effects from a few hours at 150,000 oersted and men have been exposed to 20,000 oersted for a quarter of an hour or so. Meanwhile, at the invertebrate and cellular level, there is much dispute as to whether fields can cause abnormalities in *Drosophila*, sea urchin eggs, photobacteria and ascites tumour cells though certain creatures such as the mud snail *Nassarius obsoletus* seem candidates for strange susceptibilities. (For details of these experiments and much else see *Biological Effects of Magnetic Fields* (edit. by Barnothy, M. F.), Plenum, New York, 1964). Of the various marginal effects, magneto-tropism in plants seems the best established. From these matters it is but a short step to the very strange phenomena of dowsers and bird navigation and their attendant literature, as rich in speculation as short on physical theory. Hall effects and electron interactions in proteins, perhaps, but only by wildest stretch of the imagination (and the wild stretching of imagination is common enough in such fields) attribution to physical changes in water.

So what in the end of the contented boilerman in Alma Ata and the guidance system of the mud snail? Can these

conceivably have enough in common to warrant a new, close look at the magnetophysics of aqueous systems—or should physical chemistry, with uneasy glances over the shoulder at the polywater nonsense, let this particular sleeping dog lie? For it could well be that all the various effects have but one essential in common, their ability to elicit man's tendency, active since ancient times, to relate the mystery of the magnetic force and its field to almost every other enigma that troubles him. A tendency to which a remarkable variety of scientists seem in no way immune.

From our Molecular Physics Correspondent

Continuity of Precambrian life

ALTHOUGH Precambrian microfossils have been known for many years, little attention was given to this area of investigation until after the descriptions of the microorganisms from the 1.9×10^9 year old Gunflint Chert^{1,2}, part of the Lake Superior banded iron formations from Canada. These publications appeared in 1965 and initiated the examination of many ancient rocks by scientists of various disciplines in an endeavour to throw light on the origin and evolution of living systems. This great burst of interest coincided with the scientific activities associated with the preparation for the American manned space flights and lunar landings which renewed interest in the possibilities of extraterrestrial life, its origin and possible contamination of the Earth by returning astronauts.

The problem was tackled on a broad front. The chemists investigated both the soluble and insoluble fractions of the organic matter in Earth rocks, meteorites and, later, lunar rocks. The palaeontologists examined the rocks for evidence of morphologically preserved microfossils, and found these in Earth rocks. There have never been any indications in lunar rocks of structures possibly interpretable as biogenic in origin and the bizarre, chemically organic, six-sided box-like structures from the carbonaceous chondrites have been interpreted as condensation products of abiogenically produced organic compounds³. The small hollow, spherical organic bodies also recovered from carbonaceous chondrites have been similarly interpreted⁴, and it is significant that the surface texture of the meteorite spheroids is markedly different from the surface texture of spheroids from the 3.355×10^9 yr old Onverwacht Group rocks of South Africa^{4,5}.

A survey of the earlier work can be found in Schopf⁶. Three time intervals have received considerable attention: $3.4-3.0 \times 10^9$ yr; around 2.0×10^9 yr; and from 1.3×10^9 yr to the base of the Cambrian.

In the first of these time intervals occurs the oldest, well dated, easily accessible sedimentary succession, the Onverwacht Group of the Swaziland System of South Africa. The 3.750×10^9 yr old Amitsook and Issua rocks of Greenland are less accessible, and in the case of the Amitsook, highly metamorphosed. It would be interesting to see the results of the $\delta^{13}\text{C}$ analysis on the graphite from these rocks, although the high grade of metamorphism would make interpretation of the results very difficult.

Even in the Onverwacht Group, the rocks are part of a green stone belt, they have been folded and have suffered some degree of metamorphism⁵. Nonetheless, small (up to 20μ) spheres and filaments have been found in moderate abundance in the cherts, and their biogenicity has in general been supported by the evidence of the $\delta^{13}\text{C}$ ratios of the kerogen⁷. The kerogen itself has a chemical structure similar to that of kerogens produced by degradation of known biogenic compounds⁸. Controversy centres on the older part of the Onverwacht, the Theespruit Formation. The $\delta^{13}\text{C}$ ratios of its organic matter are anomalously low

and this may imply the presence of possibly pre-biogenic or at least pre-photosynthetic vital activity⁸. This difficulty cannot be resolved however, until the effects of metamorphism by heating and by pressure on $\delta^{13}\text{C}$ ratios are better understood.

Evidence for early photosynthesis is adduced from the discovery of stromatolites in the Rhodesian 3.1×10^9 yr old Bulawayan System⁹, that is roughly the same age as the Fig Tree Group which directly overlies the Onverwacht Group of South Africa. Microfossils in the Fig Tree Group were first discovered and named by Barghoorn and Schopf¹⁰. Although some doubt has been cast on the validity of the rod-like 'bacterial' forms discovered only by electron microscopy⁶, the spheres discovered in optical thin section are regarded as reliably biogenic⁷ and further investigation of these rocks is necessary.

Until very recently, a huge gap in knowledge existed between the Fig Tree spheroids and the banded iron formation microorganisms—a time gap of nearly 1,000 Myr—but two groups have recently described^{11,12} the discovery of extremely well preserved blue green algae in dolomitic limestones of the 2.3×10^9 yr old stromatolitic Transvaal System. These algae have a remarkably modern aspect and have been closely compared with modern genera of blue green algae. These fossil assemblages are unusual in that they are found in dolomitic limestones and not in chert.

The banded iron formation Gunflint Chert assemblage^{1,2} is associated with stromatolites and is remarkably varied and modern in appearance. Walter¹³ has suggested that these may represent fossilised fumarolic hot springs deposits and that they may have been preserved in primary silica resulting from volcanic activity. The microfossils from other banded iron formations, in Australia for example, do not however, resemble the Gunflint organisms at all, and indeed are much more similar to the spheres from the much older Onverwacht and Fig Tree rocks, both in appearance and in the state of organic metamorphism. The differences may result from original facies variations, or from the very slight age difference between the Australian (2.0×10^9 yr) and the Canadian (1.9×10^9 yr) rocks.

Until fairly recently, there was nearly as large a gap in knowledge between the Gunflint assemblages and the Bitter Springs assemblages described by Schopf^{6,7} as between the Gunflint and the Fig Tree. The Bitter Springs assemblage contains many unicellular and multicellular blue green algae, and has a moderately high proportion (about 25%) of cells interpreted as eukaryotic from the presence of preserved organelles and from the type of cell division observed.

Similar cells, containing membrane-bound contents have since been reported from Beck Springs, California (1.4×10^9 yr old)¹⁴, Belcher Island, Canada (1.8×10^9 yr old)¹⁵ and, most recently, from the Bungle Bungle Dolomite, Western Australia (1.5×10^9 yr old)¹⁶. Thus the origin of the eukaryotes must be regarded as having occurred much earlier than has previously been supposed⁷. The Bungle Bungle Dolomite contains many colonial and multicellular microorganisms like the recently reported assemblage from the Amelia Dolomite of the McArthur Group of Australia's Northern Territory, also 1.6×10^9 yr old^{17,18}. Colonial microorganisms have also been recovered from the HYC ore body of the McArthur Group¹⁹, lending strength to the hypothesis that deposition of some stratiform ore bodies may be related to biogenic activity. This same view has been put forward by Lopukhin²⁰, in a review of Soviet Precambrian microorganisms and their economic importance.

Although there now seems to be some evidence for the presence of eukaryotic organisms as long ago as 1.8×10^9 yr, the assemblages from $1.8-1.3 \times 10^9$ yr interval, although very varied, are dominated by prokaryotes^{16-18, 21}. The cells described by Hoffman²¹ from Belcher Island may well represent primitive 'protoeukaryotes', as indeed may

the cells described from the older Animikie Formation of Ontario²².

New assemblages have been described from the later Precambrian^{23, 24}, and these contain cells that can reasonably be interpreted as eukaryotes thus reinforcing some of Schopf's⁶ earlier views. The enigmatic *Chuarina*, with a diameter of between 2 and 3 mm, has been redescribed by Ford and Breed²⁵, and assigned to the Leiospheridia (Acritarcha). All the recorded occurrences of *Chuarina* are from Precambrian rocks, usually shales, less than 1.0×10^9 yr old. The occurrence of these large plant microfossils seems to have stratigraphic importance. Furthermore, the Leiospheridia can be related to the present day eukaryotic Prasinophyceae.

By the very late Precambrian, complex green algae, similar to *Botryococcus* have been observed in the lower part of the Postpilitic Group from Vrané, near Prague²⁶.

These recent discoveries tend to modify earlier views⁶ that "gradually accelerating early evolutionary development, beginning rather slowly but markedly quickening with the emergence of eukaryotic organisation, seems consistent with the fragmentary evidence currently available". A model of a more gradual, steady, development seems to fit the present evidence much better. Furthermore, the new evidence includes the discovery of microfossils in lithologies other than the facies-restricted black, usually stromatolitic cherts of earlier years, and these will undoubtedly greatly enlarge knowledge of Precambrian microbiotas. Help for the painful phantom limb?

THE phantom limb is a phenomenon that has long aroused curiosity. How is it that one feels a limb that is not there? Yet once one thinks about the anatomy and physiology of the situation, one realises that phantom limbs are to be expected: all the nerves coming from the limb are still there, they still make connections at various levels of the central nervous system and, finally, these connections connect to that part of the brain where afferent nerve impulses evoke sensation. Phantom limbs occur in 95 to 100% of all people who have had a limb or part of a limb amputated.

In that other 5% or less, the limb may still be conjured up by concentrating on it, or by trying to move it.

In most limb amputations, the cut nerves end up in firm swellings called neuromata which consist of whorls of outgrowing nerve fibres surrounded and intertwined by connective tissue. One assumes that these nerve fibres are capable of working and that they frequently fire off impulses to the central nervous system. Not only is this a likely assumption, but it is reinforced by the effect of blocking the cut nerves of the neuroma with a local anaesthetic. When these nerve fibres are blocked in this way, there is a great reduction of sensation or a total loss of the sensation of the phantom limb. It is apparent that the sensation was due to the nerve fibres within the neuroma continually firing off impulses.

A few people who have had parts of their bodies amputated, experience constant pain in the stump or in the phantom, or both. In such patients, blocking the neuromata with local anaesthetics almost always temporarily stops the pain. Many suggestions have been proffered as to why some of the patients have pain and others do not. It could be caused by a difference in the make-up of the neuromata, but this is an unsatisfactory suggestion because no differences in the histological appearances between pain producing and painless neuromata have been found.

Wall and Gutnick (see this issue of *Nature*) have now induced neuromata in the cut sciatic nerves of rats and have recorded from the posterior rootlets entering the spinal cord. As was expected, they found that the nerve fibres of these neuromata were continually active. Their discharge of impulses could be increased by pressure or tapping on the neuromata and it could be stopped by anaesthetising the neuromata with local anaesthetic solution—all similar to the situation in man.

A more interesting finding was the effect of electrical stimulation of the chronically divided nerve. The nerve on which the neuroma had been induced was divided so that it no longer reached the spinal cord. Electrodes were then placed on the nerve and it was stimulated rapidly for a few seconds. This electrical excitation caused a marked reduction in the nerve's spontaneous activity, which lasted for up to an hour. This finding may suggest that if the nerve fibres can be induced to fire off maximally, they may stop firing spontaneously for a prolonged period. A similar mechanism could account for the effectiveness of one of the treatments for painful neuromata. In 1881, Granville (*Lancet*, i, 286) introduced percussion of the neuroma as a treatment for the chronic pain. This treatment was largely forgotten, revived for a short time during the 1914–18 war, forgotten again, and re-introduced by Russell (*Br. med. J.*, **1**, 1024; 1949) the results being reported by Russell and Spalding in 1956 (*Br. med. J.*, **2**, 68). Sometimes when the patient first hits his neuroma with a mallet and peg, the pain is increased; but the neuroma soon becomes numbed and the pain may then stay away for hours.

During the past few years the transcutaneous electric stimulation of nerves has been introduced for many painful conditions, including painful amputation stumps and painful phantom limbs. This treatment was based on the gate-control theory of pain of Melzack and Wall (*Science*, **150**, 971; 1965). The theory states that whether or not an input to the spinal cord finally causes pain depends on the amount of input arriving in large myelinated afferent fibres on the one hand and small myelinated and non-myelinated afferent fibres on the other. Both groups of fibres are said to affect the small neurones of the substantia gelatinosa, a part of the posterior horn very near the zone of entrance of the afferent fibres. The large fibres excite these neurones and the small fibres inhibit them. These substantia gelatinosa neurones are inhibitory. And so, when these neurones are themselves inhibited, their inhibitory action on the afferent fibres will not be exerted; a massive afferent input will enter

the spinal cord, and pain will result. When these neurones are excited, they exert presynaptic inhibition on afferent fibres, and the input to the spinal cord will be moderate; pain will not occur. Excitation of the large afferent fibres thus reduces the input to the spinal cord and is said to close the gate.

Wall and Gutnick now suggest an alternative way in which electric stimulation might act. It could do so preventing nerve impulses being fired off spontaneously, and, as it is this firing that causes both the pain and the phantom sensation, both would be stopped by electric stimulation. The mechanism by which antidromic stimulation stops impulse generation after stimulation has stopped its unknown. Wall and Gutnick suggest that the excitability of small nerve fibres within the neuroma is altered, by electric stimulation because these endings are abnormal and are not behaving in the same way as do normal nerve fibres; and they bring forward some evidence to show that this is so.

This is probably the first physiological investigation to have been carried out on a traumatic neuroma induced in an animal. It seems as if it has already thrown light on how certain forms of therapy may work; and it suggests that a similar investigation could be carried out in man, now that it is possible to record from human nerves by means of electrodes introduced into the peripheral nerves. P.W.N.

Unpredictability of comets

from a Correspondent

COMET Kohoutek disappointed many people over Christmas by being considerably fainter than predicted. Most of the blame for this disappointment can be laid at the feet of the media-men who seem to hanker after superlatives such as brightest, longest, most spectacular and are not interested in run of the mill comets and the qualified predictions of astronomers. Comets themselves, however, must also carry some of the blame as they are notoriously unpredictable. This cometary fickleness has been stressed in an article by Jacchia, who works at the Center for Astrophysics, Harvard Observatory and Smithsonian Astrophysical Observatory (*Sky Telesc.*, 47, 216; 1974).

The brightness J of a comet can be represented by the formula $J = J_0 \Delta^{-2} r^{-n}$ where J_0 is a constant, Δ is the distance between the comet and the Earth, r is the distance between the comet and the Sun, and n , the power of r , is a quantity that varies from comet to comet and, in certain cases, as a function of r . In an extensive study by Bobrov-

nikoff the mean value of n was found to be 3.3. This indicates that cometary luminosity is produced by two mechanisms; first, the reflection of sunlight from the small dust particles in the coma (if this was the only source n would be 2) and, second, by direct emission from gas molecules, thus producing band spectra. The luminosity increases as the comet approaches the Sun because of the increase in the incident radiation, coma size, gas and dust production and molecular excitation. Increases in luminosity and therefore brightness, however, do not always occur and n has been known to take values that range from -1.77 to +11.40. This variability in the power of r is indicative of the chance one takes when predicting cometary brightness. Jacchia gives as one telling example the case of comet Westphal which was observed as an 8th magnitude object on September 26, 1913. Perihelion passage was due on November 26 but instead of brightening the comet gradually faded being 13 mag at the end of October and 17 mag on November 22, 4 days short of perihelion, when it had been expected to be at its brightest.

Jacchia compares Kohoutek with comet Halley's apparition in 1910. Halley performed excellently having an n of 5 and also brightening in the post-perihelion phase. Kohoutek started well with an n of 4.0 shortly after discovery (justifying the early optimistic predictions) but n dropped to 3.0 in early November 1973 and 2.2 around December 20. At perihelion the comet shed more matter than expected and was easily photographed by the Skylab astronauts, but after perihelion the comet followed a trend one magnitude fainter than it did at the corresponding distance on the way to the Sun—exactly opposite to the behaviour of Halley's comet.

So comets seem to have two records in astronomy. Not only do they have the greatest range of brightness of all celestial objects, the great comet of 1882 being seen in full daylight 4 degrees away from the Sun and comet Wolf 1 being observed in 1942 when it had a magnitude of 19.3, but they also seem to be the most unpredictable: comet Kohoutek unfortunately lived up to this latter reputation.

Man misled by man—on ice

from our Geomagnetism Correspondent

THERE is a standing joke among palaeomagnetists about the man who spent several weeks collecting beautiful samples of baked red laterite. When he returned to the laboratory one of his more experienced colleagues coolly

Happy nuclei

Hartree-Fock calculations of nuclear matter have now advanced to the stage where they can reveal quite detailed and unexpected features of nuclear structure. This illustration shows the contour plot of the density of sulphur-32 obtained by Curry and Sprung (*Nucl. Phys.*, A216, 125; 1973).

informed him that he had drilled the brick foundations of a long-demolished farmhouse. Each branch of the earth sciences has its own variant of this story, but for glaciologists the joke seems to have come uncomfortably to life. As the recent experience of two North American scientists demonstrates, it is easy to be misled by one's ancestors even in the most unlikely of places.

Last year, Berkland and Raymond (*Science*, 181, 651; 1973) reported that they had found glacial polish, grooves and striations at a height of 1,370 m on Grandfather Mountain in North Carolina. The longest of the grooves were about 1 m long, 15 cm wide and 5 cm deep, and the 60 or so recognised examples gradually changed their trend from S80°E to S40°E from the southern to the northern ends of the exposure. This variation, Berkland and Raymond argued, indicated "two lobes of ice which formerly coalesced at the site of the outcrop and preserved it as a bastion". They then went on to calculate that the ice had maximum and minimum thicknesses of 300 m and 100 m, respectively, in the cirque containing the outcrops investigated. It is true that no moraines were observed at the cirque outlet, but this was considered neither unusual nor significant.

What was considered significant was that Grandfather Mountain lies at a latitude of about 36°N, whereas alpine glaciation in the eastern United States had not previously been reported south of the Catskill Mountains in New York state (about 42°N) and the Laurentide ice sheet ended in New Jersey and Pennsylvania between 40° and 41° N. In other words the new result suggested that Pleistocene glaciation had extended some 890 km further south in the

Appalachians than had previously been supposed. This, in turn, raised questions about other evidence which had hitherto been interpreted differently. Striated boulders and cobbles, for example, are quite abundant locally in Pleistocene river gravels of North Carolina and Tennessee and are indistinguishable from glacially striated clasts. Wentworth (*Bull. geol. Soc. Amer.*, **39**, 941; 1928) suggested the possibility of a glacial origin for these more than 40 years ago, although both he and later workers have preferred to ascribe their markings to river ice. The new discovery made by Berkland and Raymond, if substantiated, suggested that the question of glaciation in the southern Appalachians would need to be re-examined.

Unfortunately, the discovery has not been substantiated; that is to say, although there is no doubt that the grooves exist, their origin is certainly not glacial. McKeon (*Science*, **184**, 88; 1974) now reports that he has examined the grooves and has found, among other things, ferric stains in the bottom of some of them, polish on groove bottoms but not on intergroove surfaces, the absence of grooves in shallow lows of the outcrop surface, and the presence of at least one groove continuing part of the way down the outcrop's vertical face. These characteristics, he argues, suggest that the grooves are not glacial but man-made. More specifically, he suggests that the grooves are a product of stone quarrying, logging, or survey activities during the past two centuries—a suggestion strongly supported by the discovery of weathered wire cables downslope from the outcrop. McKeon also uses data from a weather station on Grandfather Mountain to show that glaciation at an elevation of 1,370 m would imply a July glacial age temperature about 18° C lower than the present July temperature—a decrease three times greater than that usually acknowledged for the ancient glacial areas.

Hack and Newell (*Science*, **184**, 89; 1974) have also visited the outcrop concerned and confirm the characteristics described by McKeon, adding that the grooves "in no way resemble the polished, striated, and grooved outcrops [they] have seen in glaciated areas". They also found the rusty steel cables, but were more enterprising than McKeon in seeking out a retired lumberman who had taken part in the last logging in the area during the 1930s. This gentleman described precisely how the grooves were formed by the operation of a steam-powered cable system, adding that similar grooves could be found "on rocks all through the woods". In short, it is clear that the grooves found by Berkland and Raymond are of more interest to industrial archaeologists than to glaciologists.

To their credit, Berkland and Raymond (*Science*, **184**, 89; 1974) openly admit that they were mistaken about the origin of the grooves, at the same time describing at length how they came to be misled. On the other hand, they disagree strongly with Hack and Newell's statement that "no need exists for philosophical discussion of the possibility of alpine glaciation" in the southern Appalachians. On the contrary, they assert that there is a wealth of physical, biological and palaeoclimatic evidence to support such glaciation, and promise that Berkland will discuss this more fully in a later publication. It is clear that, in spite of the set-back of the misinterpreted grooves, the issue of southern Appalachian glaciation is still far from dead.

Palindromes in eukaryotic DNA

from a Correspondent

GONE are the days when genomes were described solely in terms of the abundance of different repetition frequency classes in eukaryotic DNA sequences. Nowadays it is fashionable to write of the interspersion of repeated and non-repeated sequences and to formulate models of the genome based on the lengths of repeated and non-repeated elements and the extent of intermingling. Good evidence has been provided in *Xenopus* (Davidson *et al.*, *J. molec. Biol.*, **77**, 1; 1973), sea urchins (Graham *et al.*, *Cell*, **1**, 127; 1974), *Drosophila* (Wu *et al.*, *J. molec. Biol.*, **64**, 211; 1972; Lee and Thomas, *ibid.*, **77**, 25; 1973, *Necturus* and mouse (Pieritz and Thomas, *J. molec. Biol.*, **77**, 57; 1973) for such a model. Most of this work, however, has dealt specifically with the intermingling of intermediate repetitive with non-repetitive sequences and not with the fast renaturing, highly repetitive, low complexity DNA, such as mouse satellite DNA, which is thought not to contain any single copy elements over large stretches. The integration of DNA sequences of this type, known to be predominantly in centromeric DNA by *in situ* hybridisation, may be in large blocks alternating with sequences of greater complexity. Evidence in favour of this idea has come from equilibrium caesium chloride density gradient studies on the integration of low complexity satellite DNA sequences in the *Drosophila* genome (Kram *et al.*, *J. molec. Biol.*, **64**, 103; 1972).

There is a fourth fraction of eukaryotic DNA which renatures spontaneously at zero time even at very low DNA concentrations and which has received little attention until recently. Davidson *et al.*, in their paper on interspersion of repetitive and non-repetitive sequences in *Xenopus* also

found that this zero time renaturation increases with fragment size and suggest that there is a relatively small fraction of single stranded DNA molecules containing tandem self complementary sequences capable of forming intra-strand duplexes.

Wilson and Thomas (*J. molec. Biol.*, **84**, 115; 1974) now provide further evidence for the existence in eukaryotic DNA of inverted repeated sequences of the type

called palindromes by analogy with words and phrases which read the same backwards as forwards. Denatured palindromes would be expected to renature by an intramolecular reaction to form hairpin loops. The rate of hairpin formation is predicted to be very swift, depending on the number of nucleotides (*t*) separating the inversion, and should proceed at very low DNA concentrations since complementary sequences will not be diluted.

What Wilson and Thomas have done is to use hydroxyapatite, which binds double stranded but not single stranded DNA at low salt concentrations, to prepare spontaneously renaturing DNA from a variety of sources (HeLa cells, mouse L. cells, *Triturus* liver cells, and *Drosophila* flies). They show that zero time binding is independent of DNA concentration and occurs at C_0t values (10^{-5}) of the same order as the $C_0t_{1/2}$ for the reaction between poly(dA) and poly(dT). The only variable which seems to influence the amount of zero time binding is the molecular weight of the original DNA. It increases linearly with molecular weight except in *Triturus* where a plateau is reached with 60-70% DNA bound at molecular weights greater than 10^7 daltons. In HeLa DNA the maximum amount bound increased up to 80% at a molecular weight of 6×10^7 daltons.

(1) Linear palindrome; (2) cruciform palindrome (after Wilson and Thomas).

An alternative explanation that zero time binding is due to the presence of cross linkers in DNA was eliminated by a study of artificially (mitomycin) cross-

linked HeLa DNA. Although a large fraction of the DNA is made to renature spontaneously by treatment with mitomycin, electron microscopy of samples prepared in 90% formamide show a large proportion of X and Y forms, whereas untreated zero time bound DNA shows only linear molecules as predicted.

Observation by electron microscopy of spontaneously renaturing DNA after treatment with a single strand specific nuclease allows measurement of the lengths of the inverted segments. Such measurements show duplex lengths of 300 to 1,200 nucleotide pairs with a very few as long as 6,000. If zero time binding is caused by inverted sequences forming hairpins, then treatment with single strand nuclease, after prior removal of single strand ends, followed by denaturation would be expected to reduce the average molecular weight to half by digestion of the unpaired terminal loop t and also to reduce zero time binding. That neither of these predictions is fulfilled suggests that the terminal loops are resistant to nuclease probably because they are very short. Electron microscopy confirms this since no terminal loops are visible. The thermal stability of HeLa palindromes ($T_m 81.9^\circ\text{C}$) suggests fidelity of base pairing and consequently low levels of base substitution in the inverted segments. Moreover, base composition analysis (43% G+C) of HeLa hairpins shows that they have the same overall composition as total HeLa DNA.

Wilson and Thomas were able to estimate the distances separating adjacent palindromes by measuring molecules in electron micrographs and found that they are located in clusters of two to four. Individual palindromes are separated by predominantly $0.7\ \mu\text{m}$ although some are $8.5\ \mu\text{m}$ apart, but the clusters of palindromes are more sparsely distributed ($40\ \mu\text{m}$). The average spacing of hairpins can also be estimated from the slope of the curve of amount of spontaneously renaturing DNA against fragment size and shows that in HeLa cells palindromes occur every $13.5\ \mu\text{m}$ on average and they are more sparsely located in mouse L cells ($62\ \mu\text{m}$) and *Drosophila* ($75\ \mu\text{m}$). Finally, Wilson and Thomas produce evidence to suggest that the sequences flanking palindromes in mouse L cells are not a random sample of all mouse DNA sequences but are selected. When ^3H -labelled zero time bound DNA is hybridised in the presence of ^{32}P -labelled non-bindable DNA to filters containing unlabelled zero time bound DNA in conditions in which the palindromes have renatured before the reaction, observation of the renaturation of adjacent sequences is possible. Zero time bound DNA preferentially hybridises to ^3H -labelled zero time bound

DNA and not to the ^{32}P -labelled non-bindable fraction. It seems therefore that palindromes are located non randomly in the genome.

Although the evidence for the existence of palindromes is quite good, there is little idea about their functions. Theoretically a palindrome in native DNA may exist in two forms—the normal linear double helix or a 'cruciform' in which the strands have opened and formed two hairpins. A search for 'cruciform' structures in native DNA revealed nothing, however, and thus if they exist they must occur transiently or be stabilised by chromosomal proteins. One clue to their function may be gleaned from the observations on recognition sites in some nucleic acid-protein interactions; for instance, restriction enzymes and the *lac* repressor recognise relatively short palindromes. Furthermore, hairpin loops exist in transfer RNA, ribosomal RNA and perhaps messenger RNA and heterogeneous nuclear RNA and may be responsible for some of the specificity of interaction of these RNA molecules with the appropriate proteins. It is clear that as usual in science description of a phenomenon has outstripped analysis of its physiological importance.

Model interneurone in a locust

from our *Insect Physiology Correspondent*

ONE of the best known of all interneurons is the 'descending contralateral movement detector' of the locust *Schistocerca gregaria*, which is located in the brain and responds to movement in the visual field of the eye on the opposite side of the head. It is particularly responsive to small dark objects the abrupt movement of which evokes a strong brief excitation and a

more prolonged inhibition, associated with the rapid jump of the locust, mediated by motor neurones in the metathorax. O'Shea, Rowell and Williams (*J. exp. Biol.*, **60**, 1; 1974) now provide an excellent example of the way in which modern neuroanatomical techniques can be applied to the insect central nervous system in order to obtain visual preparations and intracellular recordings of neurones known previously only from extracellular records.

The position of the axon was determined by splitting the axon bundles and checking the locations of the well known response characteristics of the axon under study by extracellular recordings. Probing with microelectrodes was then continued and when the unit was penetrated and its identity confirmed by its response characteristics, the axon was marked by injection of cobalt ions through the recording electrode. Iontophoresis of cobalt ions into the axons isolated by cord splitting, followed by application of ammonium sulphide, leads to the visualisation of the axons and their branches in whole cleared ganglia.

The same procedure of microelectrode penetration of the various brain neurones until the characteristic response of the descending contralateral axon was evoked, followed by marking of the cell body by electrophoretic injection led, in favourable preparations, to the filling of the entire neurone and thus to confirmation of the results of iontophoresis of the descending axon from its lower end, and to the demonstration of its thoracic connections.

The cell body of this model interneurone is the largest in the brain, $45\text{--}50\ \mu\text{m}$ in diameter. Earlier electrophysiological studies by Burrows and Rowell had shown that it makes

Fig. 1 a, Distribution of the descending contralateral movement detector neurone in the methothoracic ganglion of the locust as inferred from electrophysiological recordings from motor neurones by Burrows and Rowell. The motor neurones are labelled: AAdC, anterior coxal adductor; FETi, fast extensor tibiae; AI, anterior inhibitory flexor tibiae; PI, posterior inhibitory flexor tibiae; CI, common inhibitory. b, The distribution as visualised by cobalt injection.

bilateral connections with various motor neurones in the metathorax (Fig. 1a) ensuring rapid extension of the tibia, with inhibition of the antagonistic flexor muscles and of other systems. The distribution of the axon in the metathorax as revealed in the paper under review (Fig. 1b) shows striking agreement with the conclusions reached by electrophysiological methods alone. There are no major branches to be seen in the metathoracic ganglia which cannot be accounted for by the known connections with motor-neurones involved in the jump. It seems likely that this is the most important function of the descending movement detector neurones. There are also restricted connections with neurones in the prothorax and mesothorax, whose role in the jump are at present unknown. There are considerable individual differences in the detailed arrangements of these neurones. Assuming, as the authors do, that these differences are genetically determined, they may well form the basis of a behaviour variance, in the population, subject to natural selection.

O'Shea *et al.* conclude by pointing out that by using the methods of iontophoresis of cobalt ions, neural anatomists could uncover rich new fields for physiological investigation.

Mapping of poliovirus receptor

from our
Molecular Genetics Correspondent

POLIOVIRUS provides one of those interesting situations in which the susceptibility of a cell to a virus may depend upon its possession of the appropriate receptor. Human cells possess the receptor and can therefore be killed by the virus; whereas rodent cells usually cannot be infected. But in human-rodent hybrid cells, possession of a human gene for the poliovirus receptor is sufficient to enable the virus nucleic acid to enter the cell and, once this first step has been taken, the virus can then multiply without the mediation of any further human gene products, the rodent genetic apparatus being sufficient for its needs. It should therefore in principle be possible to identify the human chromosome(s) carrying the gene(s) concerned with poliovirus reception by making use of human-rodent hybrids which differ in their complement of human chromosomes; when some of the human chromosomes have been shed after hybridisation, loss of the appropriate human chromosome(s) should mean that the hybrids also lose their susceptibility to poliovirus. By performing such experiments, Miller *et al.* report in the April issue

of *Cell* (1, 167; 1974) that a single human chromosome is responsible for conferring upon cells the ability to accept poliovirus.

These experiments have succeeded where earlier attempts to gain this information failed because of two recent developments; hybrid lines are now available with a high degree of homogeneity of human chromosomes (necessary to establish correlations with poliovirus sensitivity), and banding techniques can be used to identify these chromosomes from the others of the set. Virus-resistant and virus-sensitive human-mouse hybrid cells all proved to possess about the same number of human and mouse chromosomes, excluding the possibility that changes in the ratios of two genomes might be relevant in establishing susceptibility to the virus (a mechanism important in polyoma susceptibility, or adenovirus multiplication).

The chromosomes of several poliovirus resistant and sensitive lines were examined by both fluorescent Q banding, which produces characteristic striations of each human and mouse chromosome, and also by C banding, which stains principally the centrometric heterochromatin. Cell lines resistant to poliovirus lacked human chromosome 19, whereas lines sensitive to infection possessed this chromosome. This implies that chromosome 19 carries all the information necessary for acceptance of poliovirus by a human cell. This does not prove, of course, that only a single gene codes for the receptor protein; but this is the most likely interpretation of these results since the genes carried on several chromosomes were responsible, the loss of each of these chromosomes might produce the receptor-deficient phenotype. The idea that more than one gene might be involved, but that all may be located on chromosome 19, may be excluded in future experiments.

Interference in heavy ion inelastic scattering

from our
Nuclear Theory Correspondent

ONE OF THE most interesting features of heavy ion interactions is the interference effects between the different processes that can take place when the interacting ions differ by only a few nucleons. For example, if ^{16}O is scattered by ^{17}O , the neutron transfer reaction from ^{17}O to the ground state of ^{16}O gives the same emerging particles as the simple elastic scattering and so is indistinguishable from it. The corresponding amplitudes interfere quantum mechanically and if they are of comparable

New MRC unit

THE Medical Research Council set up on April 1 a Mammalian Development Unit in University College, London. Its head is Dr Anne McLaren who previously worked in the Agricultural Research Council Unit of Animal Genetics in Edinburgh. She will be assisted initially by three other senior scientists two of whom are Dr M. H. L. Snow, also from the ARC Unit of Animal Genetics, and Dr D. G. Whittingham who is at present attached to the Physiological Laboratory in Cambridge.

The unit will study the growth and differentiation of the mammalian embryo, concentrating on the expression of genes in the early post-implantation embryo. Some of this work will be done in collaboration with Professor H. Harris. Dr McLaren will continue to use mice as her main experimental animals.

Dr Whittingham plans to extend his work on the low temperature storage of mouse embryos in collaboration with Dr Mary Lyon. The practical application of this work is in livestock breeding but many experiments, such as those on the mutagenic effects of irradiation on the stored embryos, can only be done with an animal whose genetics are well understood.

The new unit is being housed in the former home of Professor H. Grüneberg's Experimental Genetics Unit which was disbanded in 1972. Its budget is £175,000 for five years, unless it expands quickly enough to need more.

magnitude this is evident in the observed elastic scattering cross sections.

Interference phenomena are sensitive to the relative amplitudes and phases of the contributing process so they can provide a detailed check of the models used to calculate them, in this case of the distorted wave theory of the interaction and the optical potentials used, as well as of the spectroscopic factors used to obtain the transfer amplitude. Many studies of elastic scattering of similar ions are being made with these aims in mind.

A group at the Max Planck Institute for Nuclear Physics in Heidelberg (Gelbke, Baur, Bock, Braun-Munzinger, Grochulski, Harvey and Stock, *Nucl. Phys.*, A219, 253; 1974) has recently obtained evidence for the occurrence of similar interference phenomena in the inelastic scattering of similar heavy ions. They bombarded ^{16}O with ^{17}O ions with energies ranging from 22 to 32 MeV and measured the cross section for the

reaction leaving a ^{17}O ion in its $\frac{1}{2}^+$ state at 0.871 MeV.

This process can take place in at least two ways. First, the energy of the interaction can simply promote the odd neutron in ^{17}O from its ground state orbit to the one corresponding to the 0.871-MeV state; this is the normal inelastic scattering mechanism. But an experimentally indistinguishable result is obtained if the odd neutron in the incident ^{17}O ion is transferred to the orbit in the target ^{16}O that leaves the resulting ^{17}O nucleus in its 0.851-MeV state. This process gives a cross section that is peaked in the backward direction whereas the former process gives one peaked in the forward direction. At the energies of this experiment both amplitudes have broad angular peaks and similar absolute magnitudes, so significant interference effects can occur.

These cross sections were calculated using the distorted wave theory and the results obtained for the dominant transfer inelastic process above are shown in Fig. 1. The overall behaviour of the cross sections is given quite well but close examination shows fine structure in the data that is not reproduced theoretically. Additional calculations were then made including the contribution from the direct inelastic scattering process, and the results (Fig. 2) show that the fine structure is at least qualitatively reproduced. A perfect fit is not to be expected because higher order processes are not taken into account explicitly in this work. Some implicit account was taken of them by multiplying the direct inelastic scattering amplitude by a factor of 1.81 and this gives a much improved fit.

This work provides convincing evidence for the presence of interference

Fig. 1 Differential cross sections for the inelastic scattering of ^{16}O by ^{17}O compared with distorted wave calculations of the one-neutron transfer process.

Fig. 2 Differential cross sections for the inelastic scattering of ^{16}O by ^{17}O compared with distorted wave calculations of the coherent addition of the direct inelastic and inelastic transfer process.

effects in the inelastic scattering of heavy ions and is likely to develop into a useful spectroscopic tool.

Gene isolation and HnRNA

from a Correspondent

HnRNA, an abbreviation for the more cumbersome 'heterogeneous nuclear RNA', has been a difficult, yet intriguing, class of RNA molecules to study. Although it was discovered in 1961, clear and formal evidence that HnRNA is a high molecular weight intermediate, or precursor, in the biosynthesis of messenger RNA has been discovered only recently. The turning point came (as J. Darnell of Columbia University, New York, explained at a symposium of the nucleotide group of the British Chemical and Biochemical Societies held in Glasgow on April 1 and 2) when it was found that both HnRNA and mRNA have the common and distinctive chemical feature of an extensive polyadenylic acid region at one end of the molecule.

These studies were made initially on the complex mixtures of both messenger RNA and of HnRNA present in a widely used human tumour cell line of epithelial origin (HeLa cells). The same type of precursor-product relationship has, however, been convincingly shown by both R. Williamson (Beatson Institute, Glasgow) and K. Scherrer (Institute for Cancer Research, Lausanne) for the biosynthesis of the specific globin messenger RNAs in the specialised red blood forming cells. Scherrer emphasised the complexity of the maturation

process of the highest molecular weight HnRNA to the end product globin mRNA even in this well defined system. The biosynthesis of the heavy chain immunoglobulin mRNAs (A. R. Williamson, University of Glasgow) may be simpler as only two well defined sizes of HnRNA occur.

In the maturation of HnRNA at least 90% of the molecule is degraded in the nucleus. Both Darnell and R. H. Burdon (University of Glasgow) described uridylyte-rich regions in this part of HnRNA. Furthermore, extensively repeated helical regions occur (Darnell).

The control of the synthesis of HnRNA is an area where it is easier to suggest mechanisms than to verify whether these mechanisms actually operate. R. S. Gilmour (Beatson Institute, Glasgow), however, is studying the induction of haemoglobin synthesis in chromatin (thus studying genes which are actively capable of being expressed) in a 'Friend' leukaemic cell, has isolated a mutant with more globin mRNA. This may be a 'transcriptional' mutant with an increased rate of synthesis of HnRNA. By contrast, the absence of α -globin synthesis in a still-born child suffering from *Hydrops foetalis* (an extreme form of α thalassaemia) is caused by the absence of the α -globin gene rather than by any fault in synthesis of mRNA (R. Williamson).

Two speakers, D. D. Brown (Carnegie Institute, Baltimore) and M. L. Birnstiel (University of Zurich) described the isolation and some properties of specific animal genes. Brown has made an extensive study of the reiterated genes coding for 5S ribosomal RNA in the South African toad (*Xenopus laevis*) and he presented new evidence of the size and sequence heterogeneity of the 'spacer' regions which alternate with the coding regions in this extensively repeated gene. Furthermore, recent sequence studies on the spacer have shown that it consists in part of many short identical or nearly identical sequences in tandem, the average repeat length being sixteen bases.

The importance of the radioactive sequence methodology was emphasised by F. Sanger (MRC Laboratory of Molecular Biology, Cambridge) when he described his recent work on sequencing DNA by radioactive methods. DNA may be labelled either 'directly' or by 'copying' methods. The first approach was used to derive two 50-long sequences in the bacteriophage ΦX ; using the second approach he described the methods for extending a primer complementary to the single stranded DNA of bacteriophage f1 using DNA polymerase to deduce a sequence of 81 residues. Undoubtedly the methods will be of very general application to many problems in molecular biology.

Photometry of Comet Kohoutek (1973f)

G. H. Rieke & T. A. Lee

Lunar and Planetary Laboratory, University of Arizona, Tucson, Arizona 85721.

Extensive photoelectric and infrared photometry of Comet Kohoutek (1973f) shows that its nucleus is 10 to 15 km in diameter and that the comet contains relatively little dust, and provides new information about the nature of cometary dust grains.

We observed Comet Kohoutek (1973f) photometrically from 0.3 to 30 μm and at heliocentric distances from 0.37 to 1.9 AU. Short of 1.5 μm , the flux consists of emission lines and sunlight scattered by cometary dust; the observations in this spectral region show that the nucleus is no larger than those of a number of other recent comets. Thermal re-emission

from the dust is dominant beyond 2 μm ; our data show that Comet Kohoutek contains relatively little dust. These two results explain why the comet was much less spectacular visually than had been expected. The data reported here provide the first large, homogeneous set of photoelectric and infrared photometry obtained for any comet, and they provide new information on the nature of cometary dust.

By necessity, most of our observations were made at very large zenith angles and are therefore less accurate than normal photometry. Single measurements are probably uncertain by at least 10% and even greater uncertainties apply to observations near 20 μm (because of the large extinction corrections at this wavelength) and to those made with a

* The measurements are identified by the centre wavelength of the filter in μm , followed by the band width. $1 \text{ Jy} = 10^{-26} \text{ W m}^{-2} \text{ Hz}^{-1}$.

12 arc s beam in the photoelectric region (because of the very diffuse nature of the comet in this spectral range).

Photoelectric photometry was carried out in the *UBVRI* system defined by Johnson^{1,2} (Table 1) and infrared observations were carried out with a number of filters (Tables 2 and 3; the absolute calibration is from Low³). The data are presented graphically in Fig. 1; the infrared data have been normalised to a beam of 13.5 arc s by means of the observed dependence on beam size of the flux at 10 μm . Scans through the nucleus of the comet at 3.6 μm and 10.6 μm (see Fig. 2) show the angular distribution of the flux to be very similar at the two wavelengths and support the use of a single correction to the beam size throughout the infrared.

To interpret these observations, it is important to know the contribution of emission lines to the flux observed in each filter. A spectrum obtained by R. E. White (personal communication) on October 16.5 shows that all the photoelectric photometry near this date should be dominated by the continuum, with the possible exception of the *U* band which may be affected by CN emission near 3,880 Å. The rapid brightening of the emission lines after this date is apparent in the relatively rapid brightening in *U*, *B* and *V*. The *R* and *I* bands should be dominated by the continuum throughout our observations. A spectrum obtained by W. Wisniewski (private communication) on December 10.5 shows that the emission lines near the nucleus are much weaker than the continuum in these two bands. Detailed interpretation of the *UBV* photometry since October must await the availability of more spectroscopic observations; when such data are available, the photometry should make it possible to refer all the measurements to a common region centered on the nucleus.

Swings⁴ has listed a large number of infrared emission lines that might be expected from comets. If these lines were strong, they would be apparent in our photometry; for example, bands of CO, CO⁺, CN, CN⁺ and N₂O should

be included in our measurement at 4.8 μm and few additional lines should be added with the wider bandpass centred at 5.0 μm . The smoothness of the spectrum in this region and between 3 and 4 μm , where many other molecular bands fall, implies that the contamination of the infrared photometry by emission lines is small. Higher spectroscopic resolution near 2.2 μm on Comet Ikeya-Seki (1965f)⁵ and near 2.2 and 3.5 μm on Comet Bennett (1969i)⁶ showed negligible contamination of the broadband photometry at these wavelengths by emission lines. The emission peaks at 10 and 18 μm are also seen in the spectra of many infrared stars and are generally attributed to dust containing silicates. The feature at 10 μm was previously detected in Comet Bennett⁷.

Our photometry allows a revised estimate for the diameter of the nucleus of the comet. The initial value of 50 km was based on photographic measurements and an assumed albedo of 0.25. But reflection from a nucleus of 50 km with an albedo of 0.25 would account for the entire signal observed photoelectrically in October with the beam of 12 arc s. Photographs of the comet at that time show that it had a well developed coma which would account for a substantial part of the flux within this beam; therefore, the diameter of the nucleus must have been overestimated. We have extrapolated our photometry to smaller beams in order to estimate the magnitude of the nucleus toward the end of October. A variety of extrapolation procedures yields a range of $14.5 > m_v > 16$; adopting $m_v \sim 15$ and assuming an albedo of 0.5 (a high albedo has been assumed because of the large ratio of gas to dust in this comet), we arrive at a revised value of 10 to 15 km for the diameter of the nucleus. In other words, the nucleus of Comet Kohoutek (1973) is probably no larger than the nuclei of several recent, bright comets⁸.

For detailed comparison, the infrared spectrum of Comet Bennett (1969i)⁷ is included in Fig. 1. If this spectrum were adjusted downwards in flux by a factor of 30, it would fit smoothly into the progression of spectra for Comet Kohoutek

TABLE 3 Additional infrared photometry on December 19.7

* 5.5 arc s beam

except that the feature at $10\ \mu\text{m}$ and the flux in the region 3 to $5\ \mu\text{m}$ are somewhat stronger in Comet Bennett. Since the dust in the two comets is evidently of roughly similar composition, we can compare the amounts of dust by correcting the fluxes for the differences in field of view and geocentric distance. The result is that Comet Bennett had about 16 times as much dust as Comet Kohoutek.

The original predictions that Comet Kohoutek might have $m_v \sim -8$ at perihelion passage were based on the observations of Comet Bennett, renormalised to allow for a nucleus about two times larger in diameter. Since the amount of matter released by a comet nucleus is proportional to the surface area, the downward revisions in the diameter of the nucleus and in the amount of dust would imply that the visual magnitude of Comet Kohoutek was overestimated by about four magnitudes. This result agrees well with the observed magnitude of Comet Kohoutek and indicates that the corrections we have applied are an adequate explanation for its disappointing performance.

The heliocentric distance of the comet in October considerably exceeds those at which infrared observations of comets were available previously⁵⁻⁹. Our measurements indicate no emission peak at $10\ \mu\text{m}$ at large distances from the Sun. This transition should be confirmed as the comet leaves the Sun; it correlates well with recent calculations that high albedo clathrate grains ejected from a comet nucleus would have long lifetimes until the comet approached to within 1.5 to 2.0 AU of the Sun¹⁰.

O'Dell¹¹ has derived an expression for the albedo of cometary dust grains in terms of the integrated infrared surface brightness and the surface brightness of scattered light in the continuum. Our data are the first which permit an accurate evaluation of this expression; they yield

$$\gamma/(1 - \gamma) = 0.16$$

where γ is the albedo. The mean absorption efficiency of the grains in the visible region is then

$$\epsilon_A = 1.0/[1.0 + 0.16 \alpha(\theta)]$$

where $\alpha(\theta)$ is the ratio of the scattering efficiency of the grains averaged over all angles to the scattering efficiency at the angle of observation, θ . Over the range of θ for our observations, $\alpha(\theta) \gtrsim 1$, so that $\epsilon_A \approx 0.8$.

The infrared observations also provide information about $\epsilon(\lambda)$, the infrared emissivity of the dust grains as a function of wavelength. The temperature of the grains is determined by $\epsilon(\lambda_{\text{max}})/\epsilon_A$ at the wavelengths, λ_{max} , where significant infrared emission occurs. At a given temperature, the spectrum of the grains is controlled by $\epsilon(\lambda)$. Infrared observations at a single heliocentric distance can be fitted by a variety of emissivity laws if appropriate values are assigned to $\epsilon(\lambda_{\text{max}})$. But observations over a large range of heliocentric distance provide much more information about $\epsilon(\lambda)$, since the evolution with changing temperature of any assumed composition and size distribution of grains must be consistent with the infrared spectra.

Major changes in the nature of the dust grains should be reflected in changes in ϵ_A . Starting in November, when there is sufficient spectral coverage in the infrared to evaluate this parameter, it remains approximately the same through the final photoelectric observation on December 9.5. Observations by Ney and Hefele¹² and Ney and Ney¹³, combined with our data, indicate no major changes in ϵ_A at least to 0.23 AU.

If the nature of the dust grains does not vary, observations over a range of heliocentric distance in principle determine a unique $\epsilon(\lambda)$. As the comet moves from 1.3 AU to 0.2 AU, the equilibrium temperature of the dust grains (defined as the temperature they would assume if $\epsilon(\lambda_{\text{max}}) = \epsilon_A$) varies from 250 K to 600 K. Therefore, the grain temperature through this range of heliocentric distance is determined by the emissivity between 4 and $15\ \mu\text{m}$. We have carried out calculations assuming $\epsilon(\lambda) = a \epsilon_A \lambda^b$ over this spectral interval and requiring that the calculated spectra agree with

the observations at 5 and $12.6\ \mu\text{m}$ (two wavelengths chosen to avoid complications from the weak silicate feature at $10\ \mu\text{m}$). We find that $b \leq 0$ gives a poor fit, particularly to the data at 0.23 AU (ref. 13) and also requires $\epsilon(\lambda) > 1$ near $3\ \mu\text{m}$. Much better results are obtained with $1/2 \lesssim b \lesssim 1$; $\epsilon(\lambda)$ then has a value of ~ 0.2 at $10\ \mu\text{m}$. In other words, if the nature of the grains has not varied with changing heliocentric distance between 1.3 and 0.2 AU, their emissivity falls from ~ 0.8 in the visible to a minimum of ~ 0.1 near $5\ \mu\text{m}$ and slowly rises toward longer wavelengths through $20\ \mu\text{m}$. Although we have implicitly assumed that all the dust grains have similar composition, most of these conclusions hold for the average properties of dust made up of several kinds of grains, as long as most of the emission

FIG. 1 Photometry of Comet Kohoutek (1973f). The spectra are identified by dates (UT) and heliocentric distances. The spectrum of Comet Bennett (1969i) from Maas *et al.*⁷ is included for comparison. Also shown are a number of blackbody curves in the infrared and a renormalised solar spectrum in the photoelectric region. a, Comet Bennett (0.64 AU); b, December 19.7 (0.37 AU); c, December 18.7 (0.40 AU); d, December 13.6 (0.56 AU); e, December 9.5 (0.67 AU); f, December 6.5 (0.74 AU); g, November 28.5 (0.94 AU); h, November 15.5 (1.22 AU); i, November 9.5 (1.34 AU); j, October 17.5 (1.77 AU); k, October 8.0 (1.95 AU).

FIG. 2 Scans through the nucleus of Comet Kohoutek (1973f) at 3.6 and 10.6 μm . The observations were made on December 19.7 with a beam of 5.5 arcs.

between 4 and 15 μm is produced by a single type of grain. The scans shown in Fig. 2 imply that a single kind of grain is responsible for the emission at both 3.6 and 10.6 μm , since different spatial distribution would be expected for grains with significantly different properties.

These specific conclusions about the dust grains should

be compared with calculations of the properties of small particles of different compositions, such as those carried out by Krishna Swamy and Donn¹⁴. At present, we do not know of any grain compositions that would have the required properties. Although grains with suitable characteristics may be found, our data favour models in which the emission between 4 and 15 μm is produced by more than one kind of grain or in which the infrared properties of the grains vary between heliocentric distances of 0.2 and 1.3 AU. Models of the first kind must explain the similar spatial distributions of the flux at 3.6 and 10.6 μm , and models of the second kind must be made consistent with the lack of variation observed in the absorption efficiency of the grains in the visible.

We thank F. J. Low and E. Roemer for discussions. R. E. White and W. Wisniewski supplied us with unpublished data and Wisniewski and F. Vrba assisted with the observations. This work was supported by NASA.

Properties of afferent nerve impulses originating from a neuroma

Patrick D. Wall

Department of Anatomy, University College, London WC1E 6BT
Department of Zoology, Hebrew University, Jerusalem

Michael Gutnick

Department of Zoology, Hebrew University, Jerusalem, Israel

Damaged nerves attempt to regenerate. The nerve membrane changes its properties, becomes spontaneously active and may be the source of pain. These impulse generators have unusual properties. They become silent after high frequency activity. This silence may partially explain the effect of counterstimulation as a pain therapy.

WHEN a peripheral nerve is cut, fine unmyelinated sprouts grow out from the central cut ends of the axons. If these sprouts fail to enter the distal part of the cut nerve, they form a tangled mass in the region of the cut. This mass, the neuroma, contains poorly vascularised connective tissue infiltrated with large numbers of the sprouts of the parent axons. The sprouts extend 1-2 mm from the parent axon and they may curve back and enter the connective tissue around the nerve of origin¹. When a neuroma occurs in man

after a peripheral nerve has been cut across and regeneration has failed, it may be a source of pain. Neuromas in man must be the source of nerve impulses and contain mechanoreceptive endings since they are always tender when gently palpated. In some cases, they produce an ongoing barrage of nerve impulses since infiltration of the neuroma with local anaesthetic abolishes pain which these patients refer to the area supplied by the damaged nerve. In spite of the clinical importance and the basic interest of neuromas, physiological studies of them have not been carried out. The physiology of the growing tips of regenerating sensory nerves has been examined² and, unlike normal axons, they were shown to be easily excited by mechanical distortion and by acetylcholine. No mention was made of ongoing activity being generated in the growing tips but it should be remembered that these regenerating fibres are surrounded by their normal surround cells unlike those in a neuroma. Immediately after normal axons are cut across or crushed, a high frequency

injury discharge is generated in all types of nerve fibres but this discharge disappears within seconds and the fibre becomes silent at least for some hours³. The study reported here was designed to investigate what happened some days and weeks after nerve section when a neuroma was established.

An in vivo-in vitro neuroma

Chronic experiments were carried out on 27 adult rats of the Hebrew University strain weighing 250–450 g. Under anaesthesia, the sciatic nerve was exposed and sectioned in the upper leg. A suture was placed around the cut end of the nerve and 5–8 mm of the nerve was drawn into a close fitting medical polyethylene catheter tube. The distal end of the tube was sealed by heat forming a chamber containing the cut end of the nerve and a length of normal vascularised nerve. The nerve chamber was replaced in the leg and the animal was allowed to recover. On examination of the animal the distal musculature was found to be paralysed and the lateral two-thirds of the foot seemed completely anaesthetised. In 6 of the 27 animals, the animal mutilated the anaesthetised part of its foot after recovery periods of 9–14 d. This phenomenon has been reported before⁴ and may suggest that the animals were suffering some form of anaesthesia dolorosa or phantom pain. If this self mutilation occurred, the animals were at once reanaesthetised, examined and killed but the results did not differ from those from non-mutilating animals who were examined 9–40 d after nerve section.

For the terminal study each animal was anaesthetised with urethane, 750 mg/kg⁻¹, paralysed with gallamine and placed under artificial respiration. The nerve chamber was exposed and microscopic inspection through the wall of the tube showed a terminal neuroma occupying the distal third of the tube with the normal nerve surrounded by loose connective tissue running proximally through the tube and out of the open end. Two 28 gauge hypodermic needles were installed in the distal sealed end of the tube for use as stimulating electrodes and as a way to perfuse solutions through the chamber. The opposite intact sciatic nerve was exposed at the same distance from the spinal cord as the neuroma so that control stimulation could be applied to the intact nerve or to acutely sectioned nerve. For recording, the caudal equina was exposed in an extensive lumbar laminectomy so that the dorsal roots of both sides were available for dissection in an oil pool. Dorsal roots were cut close to the spinal cord and small filaments were dissected free and placed on recording electrodes.

Electrical stimulation

For each animal, a compound potential was recorded on a dorsal rootlet following stimulation of the neuroma (Fig. 1a). For comparison, a stimulus was also delivered at a different time to the dorsal root ganglion region of the dorsal root from which recordings were taken. The same was done on the normal side by recording from a cut dorsal rootlet following stimulation of its ganglion and its intact sciatic nerve at the same distance as the neuroma. The earliest waves on the abnormal and normal sides which result from dorsal root ganglion stimulation were identical and represent the arrival of a volley of which the fastest impulses were conducted at 59 m s⁻¹. When the sciatic nerve was stimulated on the normal side, a delayed compound action potential was recorded because of the longer conduction distance. The earliest component of the action potential was produced by impulses whose overall fastest velocity was 54 m s⁻¹. When the neuroma was stimulated, however, a very delayed compound action potential was recorded even though the conduction distance was identical on the two sides. This compound action potential has two waves, the earliest generated by impulses with an overall fastest conduction velocity of 29 m s⁻¹ and the second with velocities up to 15 m s⁻¹. At

a higher stimulus strength, even slower components were recorded. The delay in arrival of impulses is caused by very slow conduction of impulses in the neuroma (Fig. 2a). Here two compound action potentials are shown; the later one is generated by stimulation within the neuroma and the earlier by stimulating the sciatic nerve 5 mm proximal to the tip of the neuroma. The recording was, as before, on a dorsal rootlet. The fastest impulses from the proximal stimulation arrived at 52 m s⁻¹ but the impulses generated

FIG. 1 Recordings from a dorsal rootlet originating from a neuroma (A), and from normal intact sciatic nerve (B). a—Two superimposed sweeps. The early fast wave on the neuroma side and on the normal side were recorded on centrally cut dorsal rootlets following stimulation in the region of the dorsal root ganglion of the recording rootlet, conduction distance 13 mm, fastest velocity 59 m s⁻¹. The slower waves were recorded following stimulation of the normal sciatic at a distance of 45 mm from the recording point and following stimulation of the neuroma also 45 mm from its recording point. The overall fastest velocity from the normal sciatic was 54 m s⁻¹. The velocities for the first components of the two waves originating from the neuroma were 29 and 15 m s⁻¹. Time mark 2 ms.

b—The rate of ongoing activity in a rootlet originating mainly from a neuroma on the left and of ongoing activity in a rootlet originating mainly from an intact sciatic nerve on the right. Some 10 units were being recorded simultaneously with a combined rate of 150 impulses s⁻¹. The output of a rate meter with a time constant of 3.3 s is recorded. At the interruption of the line, 2% lignocaine a local anaesthetic, was perfused through the nerve neuroma chamber in the left record and directly injected into the intact sciatic nerve in the right hand record. Following the injection into the neuroma chamber there is a brief rise of firing rate which is due to the pressure distortion produced by the injection and which was also observed if saline was injected. This is not observed on the normal side. After some seconds on both sides the firing rate drops to 20–30 impulses s⁻¹. The impulses which were not anaesthetised by the local block originated from proximal muscle and not from the normal or abnormal sciatic nerve. Time mark 24 s.

c—Recording as in (b) of the rate of ongoing activity in rootlets originating from a neuroma and from normal sciatic nerve. At the interruption of the line, the central cut end of the rootlet was stimulated at 100 s⁻¹ with maximal 0.1 ms square waves for 6 s. During this period antidromic impulses swept past the recording electrodes and entered the peripheral nerves. After the end of the tetanus, the firing rate of impulses from the normal endings rapidly returned to their control level. But, the impulses from the neuroma were depressed for a long period after the end of the tetanus.

Fig. 2 *a*, Recording from a dorsal rootlet whose axons end in a sciatic nerve neuroma. Two superimposed sweeps. The slower small wave followed stimulation of the distal tip of the neuroma. The faster wave was produced by stimulating the sciatic nerve 5 mm proximal to the distal tip of the neuroma. The time difference between these two waves implies a fastest overall conduction velocity in the terminal 5 mm of 7.5 m s^{-1} . Time mark 2 ms. *b*, Interaction between the fast and slow waves shown in (*a*). Ten superimposed sweeps. For each sweep, a stimulus was given first to the extreme distal part of the neuroma and at varying time intervals following this a stimulus was given to the nerve 5 mm proximal to the neuroma tip. It will be seen that when the second wave occurs less than 3 ms after the first, it is reduced in height because the axons are partially refractory due to impulses in the same fibres which carried the earlier wave.

5 mm in a more distal direction were delayed by a further 0.66 ms giving an overall fastest conduction velocity for this terminal part of nerve and neuroma of 7.5 m s^{-1} . Since the individual fibres in the neuroma turn and twist, it is not possible to state the exact conduction distance nor the location of the stimulation. Furthermore part of the 5 mm length in the chamber is made up of relatively normal fibres. We cannot therefore give the exact conduction velocity of fibres within the neuroma but it is evident that the fibres are electrically excitable and must have a low conduction velocity, considerably below 7.5 m s^{-1} .

Evidence that the small slowly conducted wave originating from the neuroma is carried by the same fibres as the large rapid wave originating from intact proximal nerve is shown in Fig. 2*b*. Here the stimulus to the neuroma is followed at various time intervals by a stimulus to the nerve 5 mm proximal to the end of the neuroma. The recording is made from a dorsal rootlet. Ten superimposed sweeps are shown with the interval between the two stimuli changed for each sweep. The large fast wave is reduced when it approaches to within 2–3 ms of the smaller slow wave. The reason for

this reduction in height is because the impulses from the neuroma cause the axons of the central part of the nerve to be refractory. Therefore the two waves are carried in the same fibres.

Ongoing activity

If fine filaments of dorsal rootlet were teased free and mounted on recording electrodes, it was possible to record small numbers of units and to separate single units by spike height with a window discriminator. The rest of this communication deals with the responses of single axons or small groups of axons originating in neuromas. Filaments were selected which responded after electrical stimulation of the neuroma. These filaments contained fibres which were continuously active in the absence of an intentional stimulus. These impulses originated from the neuroma since they disappeared when the nerve-neuroma chamber was perfused with 2% lignocaine to produce local anaesthesia in the chamber (Fig. 1*b*). These continuously active fibres were probably myelinated afferents of relatively small diameter because the spike height of the units was less than one-third the height of the large spikes originating from muscle spindles and it is known that there is a correlation between spike height and fibre diameter⁵. If slight pressure was applied to the neuroma either by distortion of the chamber or by saline injection, the continuously active units increased their discharge rate. Previously silent fibres with higher spike heights showed a brief phasic burst of spikes during the onset of the pressure increase. Unmyelinated afferents were not examined. Filaments of ventral roots whose axons terminated in the neuroma were examined and were found not to contain ongoing antidromic impulses from the neuroma. Antidromic impulses could however be produced in these ventral root fibres by pressure on the neuroma.

It was noted that if the neuroma was driven to a high level of activity by direct repetitive electrical stimulation, the ongoing activity ceased after the stimulation. This is a phenomenon of considerable interest but since direct stimulation might have complex local effects under the stimulating electrodes, a method of activating the terminals was used in which only antidromic impulses were used. The central cut end of the filament from which recordings were made was placed on stimulating electrodes while recording electrodes were placed more distally on the same dorsal root filament.

The impulses originating from the neuroma were recorded and fed into a rate meter and a control period was recorded (see Fig. 1*c*). The filament was then stimulated maximally with 100 s^{-1} 0.1 ms square waves for 6 s. This tetanic barrage of nerve impulses swept antidromically past the recording electrodes and entered the neuroma. Following this tetanus, it will be seen that the rate of discharge from the neuroma fell and remained low for the duration of the record. The rate of spontaneous firing was depressed for minutes in all units examined and for some units, the resting discharge did not return for more than an hour. These prolonged suppressions of firing were never observed from any intact sensory endings whose excitability and ongoing discharge returned to control levels within seconds of such an antidromic invasion.

Since a tetanus is known to hyperpolarise central terminals^{6,7}, it was thought possible that this also occurs with a high-frequency antidromic invasion of a neuroma. This was tested by electrically stimulating the neuroma at 2 s intervals with a submaximal stimulus and recording the height of the orthodromic compound action potential. It was found that the electrical excitability of the neuroma decreased following a 10 s antidromic invasion at 100 s^{-1} . This decreased excitability lasted between 50 and 110 s whereas the decrease of spontaneous activity lasted in these cases between 2 and 6 min. The shorter duration of the assumed hyperpolarisation of the neuroma compared with the dura-

tion of the decreased spontaneous activity does not necessarily mean that the two are unrelated because the electrical stimulation may have triggered impulses in more proximal and larger axon sprouts than the finer more distal regions from which the impulses might originate. It might be expected since the nerve sprouts in the neuroma are fine and intertwined that they might make contact with each other so that ephaptic interactions might occur between the fibres. To test this, recordings were made from one dorsal root filament while maximal single or tetanic stimuli were applied to the entire remaining dorsal root so that the neuroma would be invaded by a large mass of nerve impulses in many fibres other than the nerve fibres from which recordings were being made. No signs were observed of any excitation or change of the spontaneous activity in fibres which had not carried the antidromic volleys and it is apparent that no obvious interaction occurs between the sensory fibres in a neuroma. Similarly, maximal stimulation of a ventral root failed to produce an afferent discharge in the dorsal root or *vice versa*. A final difference of the generation of nerve impulses from a neuroma in contrast to normal spontaneously active endings was that the discharge stopped within seconds of cardiac arrest whereas normal endings continue to discharge for many minutes.

Therapeutic implications

It is evident that these neuromas were the source of a steady barrage of nerve impulses in certain nerve fibres and that the generator of these impulses showed unusually fragile properties, being inactivated by a tetanus and being highly dependent on blood flow. The preparation with its possibilities for perfusion is an *in vitro-in vivo* isolated group of nerve endings in which it should be possible to study the action of the ionic and chemical environment on impulse generation. In addition, the results have certain therapeutic implications. If nerve impulses of the type reported here are a source of pain in man with damaged peripheral nerves and if the generator of these impulses has a lower safety factor than that of impulses from healthy nerve endings, then it is possible that drugs might be developed which affected the pathological generator without affecting normal tissue. Of more immediate interest is the use of electrical stimulation of peripheral nerve for the control of pain. This was initiated in 1967⁸ and is being widely developed. The rationale for the therapy was the suggestion that massed stimulation of peripheral fibres of large diameter set up central inhibition and closed a central gate mechanism⁹ which decreased the

transmission from the periphery to central pathways of impulses which generate pain. It was shown that certain patients were relieved of their pain not only during the tetanic submaximal stimulation of their peripheral nerves but for long periods after the end of the stimulation whereas other patients were relieved only during stimulation. The long lasting relief was a puzzle because no prolonged inhibition of spinal cord transmission was observed in animals after stimulation ceased. Now we may have an explanation. It may be that the prolonged relief which occurred in patients with damage to peripheral nerves was not produced by central inhibition but by the antidromic invasion of the damaged nerve which contained fragile generators of impulses of the type reported here. The suggestion has been made before that part of the analgesia produced by peripheral nerve stimulation was due to peripheral nerve block⁹. This suggestion was, however, based on studies of normal subjects in which, in spite of the extremely intense (20 times threshold) stimuli which were used, no clear evidence was presented that the periphery was in fact blocked. This raises the question of how such intense stimuli are tolerated and the most likely explanation is that the preceding and concomitant stimulation of large fibres sets up central inhibitions which reduces the transmission of impulses from smaller pain-producing fibres. There is considerable physiological evidence that central inhibitions are generated by repetitive peripheral nerve stimulation¹⁰. It is now apparent, however, that in certain patients who respond with prolonged relief to stimulation of a damaged nerve and who show no relief when neighbouring nerves are stimulated, there may be a turn-off of a peripheral source of pain as well as some central inhibition.

Seismic source in East Kazakhstan

ON May 1, 1969 a seismic event occurred in East Kazakhstan which, on the widely accepted body wave magnitude (m_b): surface wave magnitude (M_s) criterion^{1,2}, would be identified as an explosion; $m_b = 4.9$ and $M_s = 2.4$ (ref. 3), giving a difference of 2.5, which is typical of explosive sources. For earthquakes $m_b - M_s$ is usually less than 1.0 magnitude unit. At several teleseismic stations the P seismograms from this event recorded two clear arrivals separated by 7.5 s, which

might indicate two explosions fired in succession. At some of these stations, however, the second arrival is clearly of opposite polarity to P and is thus probably the surface reflection pP, indicating a depth of focus of about 25 km. As this depth is outside the range of routine drilling techniques the event has been tentatively identified as an earthquake³. We show here that it definitely was an earthquake.

Figure 1 shows the P seismograms (*b, e, h*) for the event, from Yellowknife, Canada (YKA), Warramunga, Australia (WRA) and Gauribidanur, India (GBA). The YKA and WRA seismograms show two arrivals 7.5 s apart; at WRA the second arrival seems to have reversed polarity relative to P, but the YKA record shows no obvious reversal. Deconvolving to remove the effects of anelastic attenuation and

FIG. 1 Seismograms for the East Kazakhstan event of May 1, 1969 (origin time 04 h 00 min 08.7 s). YKA, Yellowknife: *a*, deconvolved trace; *b*, observed trace; *c*, theoretical trace. WRA, Warramunga: *d*, deconvolved trace; *e*, observed trace; *f*, theoretical trace. GBA, Gauribidanur: *g*, deconvolved trace; *h*, observed trace; *i*, theoretical trace. Theoretical seismograms were computed for a dip-slip double couple source, with fault plane dipping at 50° towards YKA.

of the recording system⁴ shows, however, that the second arrival is clearly reversed relative to the first at both YKA and WRA (Fig. 1*a* and *d*) and is thus probably pP. The deconvolution was made assuming a value of $T/Q = 0.2$ s, where T is the travel time and Q the attenuation factor.

The seismogram from GBA, although rather noisy, also shows two arrivals, but the separation of these is about 10.0 s, so that the second arrival at GBA cannot be pP if that arrival has been correctly identified at YKA and WRA. At GBA pP must be absent or at least very small. The deconvolved GBA record is rather difficult to interpret because of the noise but again it seems that the second arrival is reversed relative to the first.

- As the second arrivals at all three stations are of reversed polarity relative to the direct P, they are almost certainly surface reflections. If so, the depth of focus is too great for the source to be an explosion. We can however obtain further confirmation that the event is an earthquake, by modelling the seismograms. We have described⁵ the use of this technique

to model the YKA seismogram for another explosion-like earthquake which occurred about 100 km from the event of May 1. We showed that this YKA seismogram could be understood by assuming that the earthquake source was a dip-slip fault of finite size with fault plane dipping at about 50° to YKA. On this model the computed seismogram agrees closely with the observed seismogram. The YKA seismogram for the May 1 event is similar to that used in our earlier study, suggesting that the source mechanisms of the two events are similar. We have in fact used exactly the same model to compute theoretical seismograms for the May 1 event as we used earlier, except that in order to fit the P-pP delay time, the source depth has been increased from 19.4 km to 25.4 km. In addition the depth of the Moho has been increased from 23.4 km to 31.6 km, to keep the source in the crust. Figure 1*c*, *f* and *i* shows the theoretical seismograms. Agreement between theory and observation is good; in particular the model predicts the large pP at YKA and WRA and the small pP at GBA. The large arrival at GBA 10 s after P is evidently sP as predicted by the model. Because PcP is not included in the theoretical calculations, its presence in the observed seismograms should be ignored when comparing theory and observation.

Finally, the deconvolved seismograms show that the shapes of the P and pP pulses at YKA are different (Fig. 1*a*): for P the leading edge is steeper than the trailing edge, whereas for the pP the reverse is true. These differences in shape between P and pP can be explained in terms of a spreading fracture (see ref. 5). For an explosion, P and pP should have the same shape. On the simple source model assumed here, differences in pulse shape similar to those seen at YKA should be seen in reverse at GBA, which is on an opposite azimuth from the source. Furthermore the trailing edge of P should be sharper than the leading edge and *vice versa* for sP. In fact the deconvolved seismogram for GBA does not show this predicted effect. In the source model used, however, the fracture spreads symmetrically from a point of initiation in the centre of the fault plane and this is probably a simplification which needs further study.

Nonetheless, from the evidence of the relative amplitudes and the polarity of P, pP and sP at YKA, WRA and GBA, and the pulse shapes of P and pP at YKA, we conclude that the event of May 1, 1969 is an earthquake and not two explosions. This leaves the large difference $m_b - M_s$ of 2.5 unexplained; models of the type described here have $m_b - M_s$ differences of around 1.2 (ref. 5). A detailed study of the surface waves might suggest a reason for the discrepancy but such a study is virtually impossible in this case because the wave trains are mixed with the surface waves from a large ($M_s = 5.6$) Tongan earthquake. Because of this mixing it is not even certain that the M_s estimates for the earthquake of May 1 are reliable.

Cyprus: seismic studies at sea

THE experiments described here were carried out in October 1971 on MV *Researcher* during a cruise in the eastern Mediterranean with personnel from the Department of Geodesy and Geophysics, University of Cambridge. Figure 1 shows the location of reflection surveys G and H, planned as a detailed study of the south-western boundary of the alleged Turkish plate, which is drawn by McKenzie as an arc around the south side of Turkey^{1,2}. Two short refraction lines X and Y were placed in Famagusta Bay and Morphou Bay respectively to trace the extent of the rock formations already distinguished by seismic methods on land⁴.

The reflection system comprised a 30 cubic inch air gun fired at 2,200 pounds per square inch at 10 s intervals into a Géomécanique hydrophone array with three active sections each 100 m long. An 8 kJ sparker was also used. The refraction experiments used the single ship radio sonobuoy technique with Cambridge radio telemetric buoys⁵.

The surveys carried out close to Cyprus penetrated only 0.6 s of sediment during sparker runs on G₃, G₄ and Grid H, but reached 2.5 s when the air gun was used on G₁ and G₂ (Fig. 1) (two-way times are quoted throughout). On Grid G there is an undulating upper reflector, A, which occurs within the unconsolidated sediments. It lies above a horizon, B, which is disturbed by folding, and which is 1.5 s below the sea floor. Below this there is a more intensely folded horizon, C, at 2.5 s (Fig. 2). B is probably the top of the 3.0 km s⁻¹ layer observed on refraction line X in Morphou Bay, and C can be correlated with the top of a 4.4 km s⁻¹ layer previously recognised as a limestone bed⁶, but correlated here with pillow lavas (Table 1).

Sediment thicknesses seem to be greater in the north and east towards the continental rise of the Gulf of Antalya, where deep basins occur. There is evidence of quite recent tectonism in this area, with depositional and compaction processes tending to smooth out the surface topography. There are some rather unusual topographic features along G₄: lenses or domes 2–6 km long show internal stratification, and the adjacent sediments are transparent (Fig. 3). It is possible that these domes represent olistoliths transported over a long distance from the Turkish shelf. Alternatively, they may be local sediment lenses, isolated by current action.

FIG. 1 Location of seismic experiments near Cyprus, superimposed on bathymetry of Carter *et al.*, 1972 (ref. 3). Contour interval 200 m.

FIG. 2 Line diagrams of reflection profiles on survey area G drawn from west to east. Two-way times are in s, the arrows mark course alterations.* Enlarged section shown in Fig. 3.

Further to the east, transparent knolls 10–40 m high alternate with stratified subsiding basins. The layers thin out against the steep margins of the knolls, indicating that the latter are rising, so it is possible that their origin is diapiric. In this case, the other stratified domes may be areas of marginal sediment deposition which have been isolated by the subsidence of larger knolls or possibly saliferous diapirs 8 km across, due to solution effects, and thus producing the features shown in Fig. 3. Over Grid H a sequence of basins and swells similar to that of Grid G can be identified (Fig. 4) where the rocky basement is first submerged below ponded sediment and then rises to form a hummocky bot-

FIG. 3 Topographic features on G₄ showing diapiric type structures, and stratified domes* to the west. The position of the section is marked* in Fig. 2. Two-way times are shown.

tom topography. Two reflectors are recognised at the north-eastern end of lines H₁, H₂ and H₃, which may correspond to the upper boundaries of the layers with refraction velocities of about 3 and 4 km s⁻¹ observed on refraction lines X and Y.

A correlation of the areas of deformation occurring over survey areas G and H was attempted, and it seems that a zone of deformation exists on the western side of the lines, which coincides with the areas of deepest water (Figs 1, 5). The deformation possibly represents a north-west-south-east trending fault, described by Giermann⁷ and Wong *et al.*⁸, but at the northern end the deformed area lies further to the west than these authors have proposed. Widespread tectonic activity seems to be associated with this faulting, because the structural features already described on survey G lie immediately behind and to the east of the fault. The deformed area falls within a broad band of seismic events. Furthermore, on both grids G and H there is good correlation between a broad negative magnetic anomaly and the fault zone, the negative anomaly separating two areas of

TABLE 1 Correlation between velocities measured for Cyprus on land and at sea (sources are indicated by the references)

	Velocity on land (km s ⁻¹)				
Outcrop ⁴	In formation ¹⁰	Laboratory ¹¹ (0-2 kbar)	Velocity at sea (km s ⁻¹)	Formation	Correlation with oceanic crust ^{12,13}
2.9	3.3	2.9-4.3	2.1	Upper sediments	Layer 1
3.7			3.3	Pillow lavas	Layer 2
4.8			4.4, 4.5		
4.9, 5.1	5.1	4.9-5.7	4.4	Basal group	Layer 2
5.5	6.4		5.5	Diabase	Layer 3
			6.5	Gabbro	Layer 3

positive anomalies to the north and south. Thus the fault is indicated by reflection, seismicity and magnetic data. If the western boundary of the Turkish plate is delimited by this fault, then the boundary would pass from the west coast of Cyprus, north-west towards Rhodes and the Gulf of Fethiya (Fig. 5), rather than due north to the Gulf of Antalya as drawn by McKenzie^{1,2}.

Fig. 4 Line diagrams of sparker reflection profiles, survey H, drawn from west to east. Two-way times are shown.

There have already been refraction experiments on land to measure the seismic velocities at outcrop of rocks in the Troodos complex⁴. In an attempt to correlate these with velocities at sea two short lines X and Y were placed in Famagusta Bay and Morphou Bay. These repeated the seismic experiments of HMS Challenger in 1952 (ref. 6), but over a greater range.

Results are presented in the form of travel-time graphs and structure profiles (Figs 6, 7). The structure on line X seems to dip down towards the south, because apparent

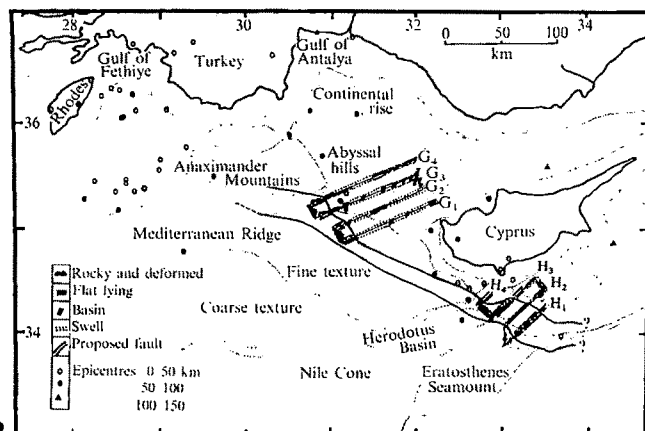

Fig. 5 Correlation of provinces over G and H to show areas of deformation, which correspond to a negative magnetic anomaly, and which possibly constitute a fault zone. Earthquake epicentres are shown. Physiographic provinces after Lort (1972) (ref. 14).

velocities along X-R, shot from north-east to south-west, are substantially lower than on X. A layer of 5.5 km s⁻¹ is detected when shooting from the north end, whereas a 6.5 km s⁻¹ layer is reached at the southern end. Otherwise, the velocities reverse to give a dipping layer solution as shown in Fig. 7a with velocities of 2.1, 3.3 and 4.4 km s⁻¹. On line Y the topography is extremely irregular so that a large scatter is observed in the arrivals and topographic corrections were necessarily large. A velocity of 2.8 km s⁻¹ is detected from second arrivals only on line Y, (A' in Fig. 6b) which is in fact a multiple of the 3.0 km s⁻¹ refractor by reflection within the upper thin sediment layer. The structure profile is shown in Fig. 7b, with velocities of 1.7, 2.9 and 4.5 km s⁻¹. The last layer was only reached on the reverse line Y-R. A comparison of the Researcher results

FIG. 7 Comparison of crustal structure profiles near Cyprus obtained by HMS Challenger in 1952 (ref. 6), and MV Researcher in 1971. *a*, line X in Famagusta Bay; *b*, line Y in Morphou Bay. The layer thicknesses are calculated at each end of the profiles as indicated.

with those of Challenger shows a similarity in general structure but deeper penetration on profiles X and Y-R (Fig. 7). A correlation between velocities measured on land and at sea can be seen in Table 1. On line Y, the 4.5 km s⁻¹ layer is tentatively correlated with the pillow lavas which also outcrop on the southern edge of the bay⁹. They are supposedly quite thick as no material of greater velocity is detected even at a range of 22 km. The velocities of 5.5 km s⁻¹ and 6.5 km s⁻¹ probably correspond to layer 3 velocities.

It is apparent from the table that velocities measured in the rocks¹⁰ at outcrop⁴ are generally lower than those obtained in the laboratory¹¹ or at sea. This is undoubtedly an effect of the difference in confining pressure on the rock units in the two environments^{4,10}, and also of the shattered nature of the outcropping units. These results are thus compatible with the widely accepted proposal that Cyprus is a section of oceanic crust¹⁰⁻¹³.

This work was supported by a grant from the Natural Environment Research Council. We thank the officers, crew and scientists of MV Researcher, and also Dr D. H. Matthews and Dr W. Q. Limond.

Flysch-ophiolite successions: polarity indicators in arc and collision-type orogens

Arc systems formed above subduction zones show a characteristic Benioff zone along or within which the subducting plate descends. In modern active arcs the polarity is indicated by the relative position of the volcanic arc and trench, by changes in the K₂O/SiO₂ ratio across the volcanic arc¹, and commonly by arc curvature. The polarity of ancient arcs can be determined by variations in the K₂O/SiO₂ ratio in volcanic arcs or their plutonic granodioritic equivalents², by recognition of parallel ophiolite and magmatic belts, or by the presence of paired metamorphic belts³. The polarity in many ancient arc systems, and also in collision-type orogens, is, however, uncertain either because magmatic arcs are poorly developed or because the relative positions of the paired belts have been confused by tectonic movements.

I suggest here that in some arc systems, the polarity can be determined by the predominant younging direction of flysch-ophiolite successions. In collision-type orogens, the polarity is indicated either by the younging direction of the flysch or by the direction from which the flysch is overthrust.

Recent work on Barbados⁴ provides evidence of the mechanism of underthrusting and deformation within pelagic sediments and turbidites deposited on the ocean floor and carried into the subduction zone. As these flysch-type sediments approach the subduction zone a thrust plane inclined towards the zone develops, cutting the sediments at a low angle (Fig. 1a). Continued subduction and underthrusting results in emplacement of the sediments overlying the thrust plane in a tectonic wedge above the subduction zone. Younger sediments deposited on the subducting plate further away from the plate boundary are in turn cut by a further thrust plane as they near the subduction zone, and are underthrust by still younger sediments. A tectonic pile of sedimentary wedges results, in which the overall age of the flysch increases towards the over-riding plate. Within each tectonic wedge, however, the age of the sediments decreases in the same direction (Fig. 1b).

Major belts consisting largely of late Mesozoic or Cainozoic flysch, deformed in a style similar to that of Barbados, occur in some other active or recently active arc systems, for example the Sunda-Burma arc⁵, southern Alaska⁶ and north-west Borneo^{7,8}. Within these belts part of the ophiolite sequence serpentine-gabbro-dolerite-pillow lavas, overlain by radiolarian cherts, is locally present beneath the flysch, forming a 'eugeosynclinal' association of lithologies. The ophiolite sequences can be interpreted as part of the oceanic crust from the subducting plate, scraped up and emplaced together with the overlying flysch above successive thrust planes (Fig. 1c).

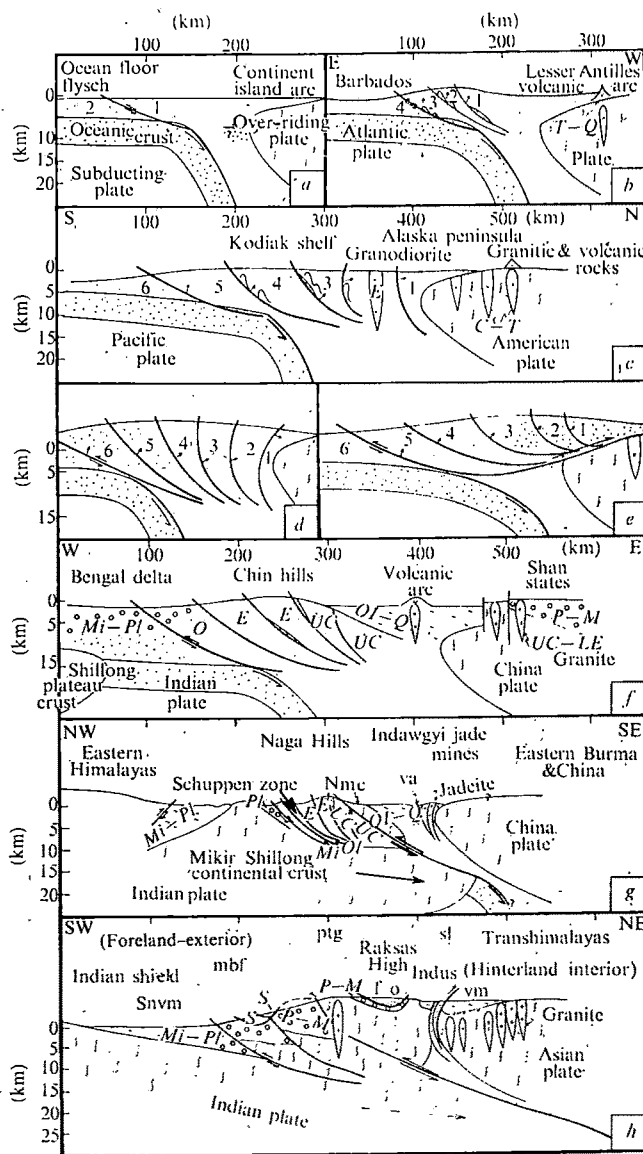

Fig. 1 Schematic simplified cross sections through Cinozoic arc systems and collision-type orogens. Locations of cross sections shown in Fig. 2. *a*, Initial underthrusting during start of subduction (no known example); *b*, Barbados (modified from Westbrook *et al.*⁴); *c*, southern Alaska showing plutons intruding flysch (modified from Moore⁹ and (Martin)¹⁹; *d*, overturning of flysch due to progressive steepening of thrust units (no Cinozoic example known); *e*, tectonic emplacement of flysch on overriding continental margin (no Cinozoic example known); *f*, Chin Hills, Upper Burma (Modified from Brunnschweiler¹⁴ and others (references in Mitchell and McKerrow)²⁰; *g*, Naga Hills, Upper Burma (Modified from Brunnschweiler¹⁴; Nmc, Naga metamorphic complex; va, volcanic arc; *h*, Kumaon Himalayas. (Modified from Gansser)¹⁶. Alpine terminology in parentheses; Snvm, Siwaliks non-volcanic molasse; mbf, main boundary fault; ptg, post-tectonic gneiss; f-o, flysch and ophiolites; sl, suture line; vm, volcanic molasse. Possible sequences of events in one arc system: *a* → *b* → (*c* or *d*) → *f* → *g*; *a* → *e*; *a* → *b* → *f* → *h* if flysch absent throughout subduction. ~, fluviatile and molasse facies; open circles, shelf or delta top facies; heavy dots, ophiolites; faint dots, flysch; S, continental crust of subducting plate; f, continental or island arc crust of over-riding plate. 1, 2, 3 . . . , successively younger flysch units. Arrows indicate younging direction. P, Palaeozoic; M, Mesozoic; C, Cretaceous; T, Tertiary; E, Eocene; Ol, Oligocene; Mi, Miocene; Pl, Pliocene; Q, Quaternary; L, lower; U, upper.

Within some flysch-ophiolite belts granodioritic or granitic intrusions slightly younger than the flysch are present. An example occurs in southern Alaska, where early Tertiary

granodiorites intrude the older part of a belt of tectonically repeated late Mesozoic and Cinozoic flysch with minor ophiolites. Here the flysch youngs mostly northwards within each tectonic unit. These 'post-tectonic' plutons represent magmatic arc activity above a Benioff zone which either increased its inclination or migrated oceanwards relative to its position during the Cretaceous⁹ (Fig. 1c).

An example of a deformed flysch-ophiolite succession in an ancient orogen is provided by the Lower Palaeozoic succession of the Southern Uplands in Scotland, where imbricate successions of north-westward-dipping turbidites overlie pillow lavas and cherts¹⁰. In Ireland, in part of the western continuation of the Southern Uplands the turbidites are overturned to the north (A. E. Phillips, personal communication). This overturning possibly resulted from progressive steepening of the already emplaced tectonic wedges during underthrusting by younger sediments (Fig. 1d).

In the southern Alaska flysch belt there is evidence that the thrust planes converge downwards towards a zone inclined beneath the continent⁶. It is possible, however, that in some other arcs the thrusts could converge in a plane of decollement, convex downwards, resulting in overthrusting of the flysch belt onto the continent (Fig. 1e). A possible example of this is found in the Patagonian Andes, where Mesozoic flysch is thrust eastwards over a miogeosynclinal succession and volcanic belt¹¹.

The flysch successions considered can be interpreted as submarine delta fan deposits which accumulated mostly on the ocean floor and perhaps partly in a trench. In some arc systems in which little flysch reaches the ocean floor, for example the Ryukyu Arc, a thick succession with a seismic velocity typical of sediments is present on the arc side of the trench¹². This succession possibly consists largely of pelagic sediments tectonically emplaced in a similar way to the flysch, although analogous thick belts of tectonically repeated pelagic successions are rare in ancient orogens.

In the Cinozoic arc systems considered, the polarity is invariably indicated by the predominant younging direction of the flysch within each thrust slice, which is towards the over-riding plate. The flysch is commonly tightly folded and overturned adjacent to, and particularly above, thrust planes. But where the thrust planes themselves are overturned as a result of oversteepening the flysch still youngs towards the over-riding plate.

Evidence for successive underthrusting of flysch-ophiolite wedges in arc systems suggests that a similar process could affect continental crust and overlying shelf sediments which are underthrust prior to and during continental collision.

In the Cinozoic Burman arc, which developed above an eastward-dipping Benioff zone, delta top sediments have been underthrust beneath the flysch-ophiolite belt of the Chin Hills^{13,14} (Fig. 1f). Further north, continental crust of the Indian Shield, exposed in the Mikir Hills, is underthrusting

Fig. 2 Locations of cross-sections shown in Fig. 1 and of localities referred to in text. Arrow points towards known or inferred subduction direction. *b*, Barbados; *c*, southern Alaska; *f*, Chin Hills; *g*, Naga Hills; *h*, Kumaon Himalayas; 1, north-west Borneo; 2, Southern Uplands; 3, Patagonian Andes; 4, Ryukyu Arc; 5, Swiss Alps; 6, northern Alaska.

deformed flysch and ophiolites of the Naga Hills (Fig. 1g)¹⁵. Shelf sediments of the Indian plate are involved in thrusting in the west, and in the east the Naga metamorphic complex is thrust westwards over the flysch¹⁴. The metamorphic complex can most simply be explained as an upthrust slice of the continental Indian plate. This requires that the continental crust of the Indian plate has overridden the original subduction zone, the position of which is shown in Fig. 1f, and underthrust the continental part of the China plate (Fig. 1g). The belt of jadeite-albite dykes and glaucophane schists at Indawgyi Lake can then be interpreted as oceanic crustal rocks dragged downwards along or above the Benioff zone, and subsequently thrust upwards together with the metamorphic complex.

Although flysch is largely absent in the Kumaon Himalayas¹⁶, the Himalayan structural setting broadly resembles that of the Naga Hills, and can be explained by northward subduction followed by underthrusting of the Indian Shield towards and beneath Tibet¹⁷. Metamorphic rocks and shelf sediments within thrust slices in the Kumaon Himalayas¹⁶ represent tectonic wedges of the Indian Shield and overlying shelf deposits, and the Raksas High, south of the Indus Suture, is possibly a tectonic slice of the Indian Shield analogous to the Naga metamorphic complex in Burma (Fig. 1h). 'Post-tectonic' granites in the Himalayas may have resulted from the final stages of subduction along the original Benioff zone, the inclination of which approached the vertical as a result of the slowing down and stopping of subduction.

In the Naga Hills collision-type orogen, as in arc systems, the polarity is indicated by the younging direction of the flysch. Where, however, the flysch either dips at low angles, or shows no predominant inclination, as in the Kumaon Himalayas, polarity is indicated by the direction of overthrusting, which is directed towards the subducting plate¹⁷.

In the complex collision belts of the European Alps, overthrust slices of metamorphic rocks and shelf sediments, analogous to those present in the Himalayas and Naga Hills, can be interpreted as tectonic wedges of the underthrusting continent on the subducting plate, rather than crustal flakes from the over-riding plate¹⁸. In the eastern Alps the northward direction of thrusting of the ocean floor rocks suggests that the polarity, or direction of underthrusting, was to the south rather than to the north as required by the flaking model¹⁸, although it is possible that, at depth, the Benioff zone dipped to the north. The Alps are complicated by major gravity slides, but the relative positions of structural units resemble those of similar units in the Himalaya¹⁹ or Naga Hills collision belts (Fig. 1g and h). The contrast between the predominant metamorphic thrust units in the Himalayas, and the flysch-ophiolite successions in the Naga Hills and many of the Alpine chains, indicates that delta fan deposits were absent in the Tethys ocean north of India during the Cretaceous and early Tertiary.

Structures similar to those formed in a continent-continent collision could result from the collision of a continent on a subducting plate with an island arc on the over-riding plate. In northern Alaska northward overthrusting of the Brooks Range miogeosynclinal succession by similar shelf facies, and by Jurassic flysch and ophiolites of the Koyukuk geosyncline to the south^{19,20}, possibly resulted from attempted southward subduction of the miogeosyncline beneath the flysch. The Tintina Trough could then represent the suture line, analogous to the Indus Suture, between the Koyukuk flysch to the north, and a late Jurassic subduction-related island arc complex in the Ruby geanticline on the over-riding plate to the south.

Flysch-ophiolite successions are present in many Phanerozoic and Late Precambrian orogens, some of which can be interpreted as arc systems and others as collision belts. The younging direction of the flysch in both types of orogen,

and the direction from which the flysch was thrust in collision-type orogens, can indicate the subduction direction and hence the polarity of parts of these orogens. Evidence for polarity, essential to interpretations of the orogens, is of increasing use in the search for mineral deposits related to magmatic arcs and of indirect use in petroleum prospecting within and adjacent to the younger orogens.

I thank Dr H. G. Reading for discussion and Dr N. A. Rupke for comments on the manuscript.

Hot spot in France?

THE hypothesis of hot spots is central to many discussions about volcanism; it was first put forward by Wilson¹ and has just been reemphasised by Morgan² who proposes that a hot spot corresponds to the top of a plume raising from the deep mantle³. As a plate drifts above it, volcanic activity takes place, giving rise to a linear chain structure with a uniform progression of ages from the active head in a direction defined by the reversed absolute drift velocity of the plate.

The best studied example is the Hawaiian volcanic island chain. More recently, Wilson and Burke⁴ have proposed a hot spot origin for many volcanic structures on ocean floors and on continents. So the concept of hot spots cannot always correspond to a deep mantle plume but may be related to a thermal inhomogeneity located only in the asthenosphere. A uniform progression of ages along one azimuth is still expected, however, unless the plate involved is stationary relative to the mantle.

Could volcanism in France be associated with a hot spot? We do not give a clear-cut answer to this question here; rather we emphasise that no simple cinematic linear model is consistent with the ages of the volcanic provinces (Fig. 1) associated with the Massif Central. Schematically, the pattern has three branches diverging from a centre of volcanism, 20 Myr old, the Cantal; the extreme end of each branch is characterised by recent activity. Similar patterns have been

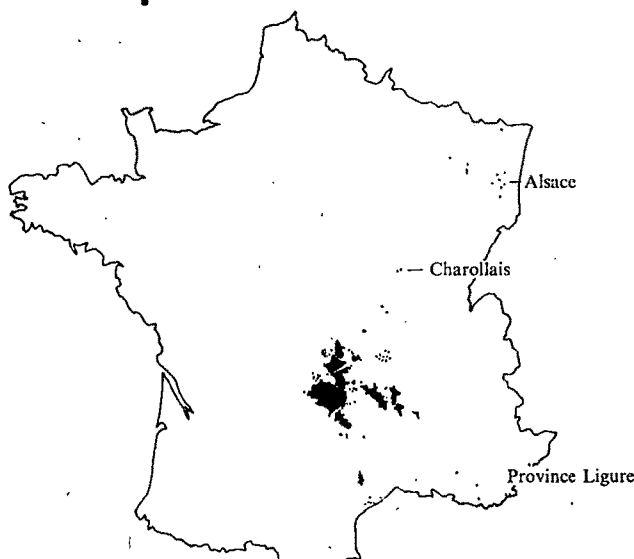

FIG. 1 Volcanism in France.

analysed by Dewey⁵. On a wider scale, however, some linear age progression is evident.

Between 20 and 13 Myr ago volcanic activity was not very prevalent. The formation of the Cantal caldera was probably connected with abundant pyroclastic emissions between 13 and 7 Myr ago. Important basaltic or trachyandesitic lava flows also took place and phonolites appeared around 8 Myr ago (ref. 14). We follow this, first, along the northern branch: the Mont-Dore started with a pyroclastic phase 8 Myr ago and true rhyolitic outflows only began 2.2 Myr ago; the activity stopped 0.4 Myr ago (ref. 15). The corresponding rectangle in Fig. 3 illustrates the geographical spread to the north and the age interval involved. Further north the Chaîne des Puys started 0.15 Myr ago (R.B., H.B., and A. Rudel, personal communication) and was still active in 80 B.C. (ref. 16). As radiogenic dating is not available for the Cézallier, the corresponding rectangle on Fig. 3 is not well determined. From its morphology, this province seems to be older than Mont-Dore.

Simultaneously, the southern branch started 13 Myr ago in Cantal, where the overall activity stopped about 3 Myr ago (ref. 12). Next came the Aubrac and then several well aligned provinces¹⁷⁻¹⁹ down to the coast near Agde, where the most recent outcrops are dated 0.7 Myr. (ref. 9). Younger outflows further south may have been buried on the crumbled floor of the Mediterranean Sea.

The third branch spreads to the south-east and is made up of two distinct echelons: the Velay-Coiron alignment (which stopped being active at 4 Myr (ref. 20)) and further south of the Devès-Ardèche, in which province the most recent basaltic flows took place about 12,000 yr ago, (ref. 21; Fig. 3).

Before describing the age and space structure of the Massif Central in more details, we note the existence of two other distinct volcanic phenomena in France (Fig. 1). In the Ligurian province, the andesitic rocks dated 26 to 29 Myr (ref. 6) originated at the end of the Oligocene and are probably associated with a past subduction zone⁷. Rift volcanism is well known on the sides of the Rhine graben (between 80 and 0.4 Myr (refs 8 and 9)). There are other graben formations to the south-east of the Rhine valley forming an *en échelons* pattern (Fig. 1): the Charollais graben also shows Eocene volcanic outcrops dating from 60 to 30 Myr ago (ref. 10); no volcanism is known in the Dombes graben. The Roanne-Montbrison graben is also volcanic, and finally the Limagne has volcanic outcrops both on its central axis (22 to 3 Myr (ref. 11)) and along its granito-metamorphic sides.

Thus subduction, on the one hand, and graben formation in connection with the alpine tectonics involving a possible shearing or extension between the Hercynian platform and the Alps, on the other, are able to explain the volcanic activity described, the total volume of which is rather modest by comparison with the Massif Central.

The spreading of volcanic activity along the three branches of the Massif Central can be analysed on the basis of Fig. 2. An initial outflow took place 21 Myr ago¹² at the limit between the north of Cantal and the Cézallier massif. This location lies at the north-west end of an Hercynian horst containing the only known peridotite residuals of the region¹³, witness of a very old (Cambrian?) suture. We take it as the geometric origin of volcanism, noting, however, that other Lower Miocene, mainly basaltic, outcrops have been dated all around the Cantal massif in direct contact with the crystalline basement.

We do not discuss here the important question of the chemical evolution of magmatism with time or structural location. The facts we stress are the following: (1) As far as volume of emission is concerned, the provinces associated with the Massif Central are the dominant feature of volcanism in France. (2) Activity has spread along three arms around

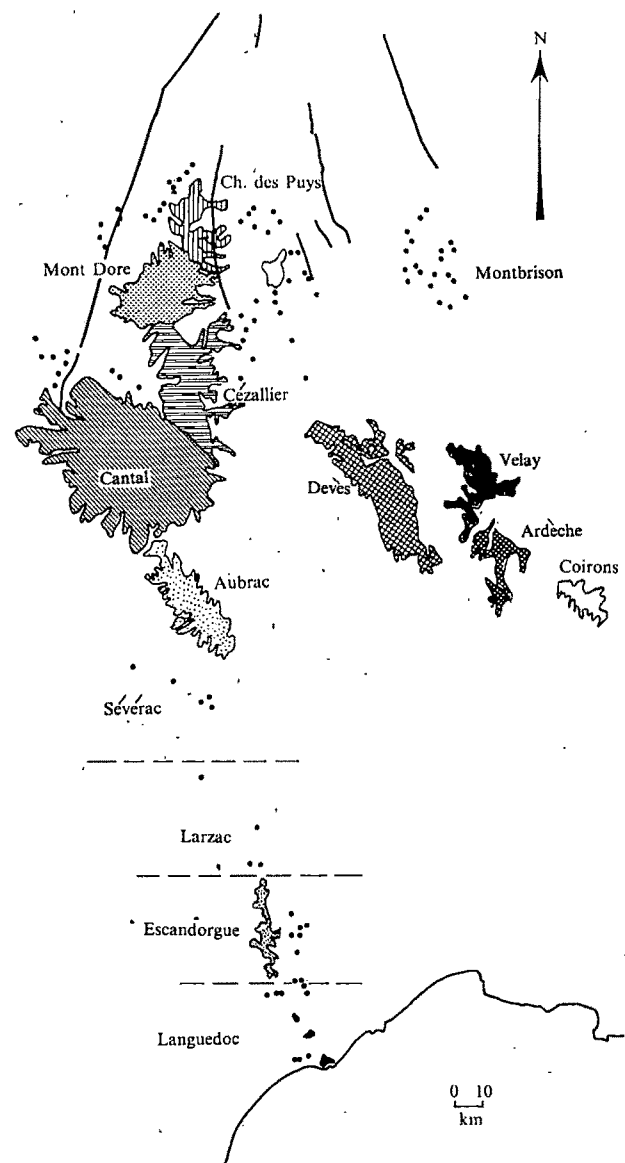

FIG. 2 Volcanism of Massif Central, Causses, Escandorgue and Languedoc. Each volcanic district is represented with a specific graphical design. Each of them is represented by the same specific graphical design in Fig. 3.

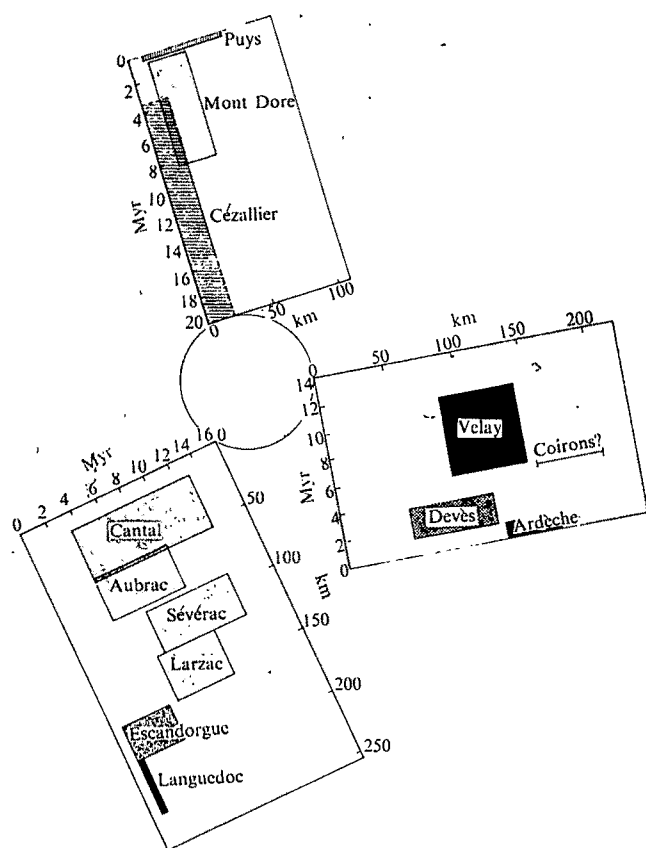

FIG. 3 The great circle represents the situation of the starting point of French volcanism 20 Myr ago. Each of the three rectangles is respectively a diagram of the three branches along which volcanism spreads. Inside the big rectangles, small ones are measured in time (Myr) representing activity within a province (duration of volcanic activity) and in km (distance of the province (proximal and distal edges) from the starting point).

the region of initial volcanism in Cantal dated 20 Myr. If this spreading is assumed to have started 13 Myr ago, the average spreading velocity can be estimated from Fig. 3 to be 0.6, 1.7 and 1.0 cm yr^{-1} along the northern, southern and south-eastern branches respectively. Although the accuracy of these figures is poor, the difference between them is real. (3) The volume of volcanic products emitted decreases approximately exponentially from Cantal to the extreme end of the three branches. For example the Cantal massif is about 10 times as big as the Mont-Dore, which is in turn about 10 times bigger than the Chaîne des Puys.

So we conclude that the age and space structure of the Massif Central does not exclude or prove the presence of hot spot under the European lithosphere in this area. It certainly does not yield a quantitative knowledge of the drift velocity of the European plate with respect to the asthenosphere beneath it.

Returning to the general distribution of volcanic centres in France, the age of initiation of rift volcanism progresses quite uniformly as one moves from the Rhine graben (80 Myr) to the Charollais (60 Myr), the Limagne (22 Myr) and finally the southern branch of the Massif Central, which lies along this general trend. It is tempting to connect this with a hot spot. The spreading velocity of the latter would be non-uniform, averaging about 1 cm yr^{-1} . Such a proposal immediately raises questions: What is the relationship between volcanic activity and tectonism? Why does the magmatic activity last for so long after the initial phase? What causes the occurrence of a paroxysm in the activity around 13 Myr connected with the initiation of a three-branches pattern? Finally, there are difficulties in reconciling this overall

north-south trend with the suggestions of Duncan *et al.*²² of an east-west progression of volcanic activity from Poland to the Eiffel and a south-north migration from Scotland to Ireland. Dating and magmatic studies on a large scale at the periphery of the Alps is vital if a comprehensive model of volcanism on the European plate is to be built up.

Glacial and postglacial sedimentation in the Sea of the Hebrides

SHALLOW seismic profiling, sediment coring and drilling from an anchored ship have provided new information about sedimentation in the Sea of the Hebrides. Some initial results are summarized here.

On shallow seismic profiles over the inner continental shelf (east of 08°00'W, Fig. 1) a principal reflector, coincident with a stratigraphic unconformity, is interpreted as a rockhead reflection. This surface is obviously glaciated¹, overdeepened trenches are common, and where it crops out it is smoothed and striated². The layer above this reflector is, therefore, interpreted as Quaternary sediment. Its thickness has been calculated assuming a seismic velocity of 1.8 km s^{-1} and isopachytes are shown in Fig. 1. Cores and boreholes through this layer have recovered the following lithologies.

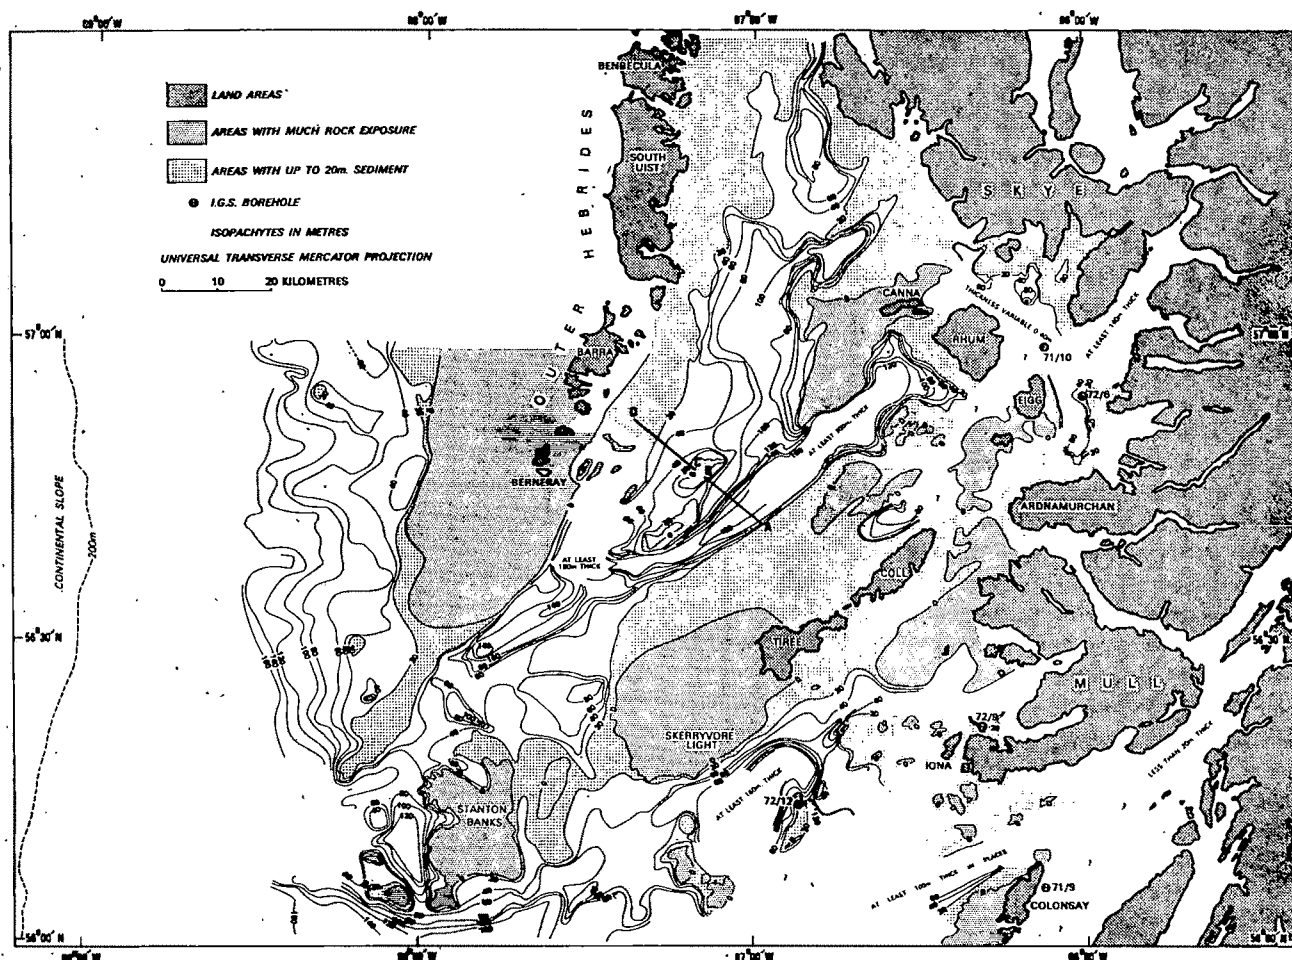

Fig. 1 Isopachytes on Quaternary sediment.

Formation 1. Till (Fig. 2) constitutes only a small proportion of the total sediment encountered in the boreholes. Reflections from the surface of moraine hummocks are seen on some seismic profiles (Fig. 3) but more commonly the profiles fail to record a boundary between Formations 1 and 2. This may be due to lack of velocity contrast between the two or to an insignificant thickness of Formation 1.

Formation 2. These firm, poorly sorted sandy muds³ (Fig. 2) contain variable amounts of granule and pebble grade lithic fragments⁴. Benthonic foraminifera are sparse but there is a significant dinoflagellate cyst population.

Lithology (compare with refs 5 and 6), stratigraphical position beneath late glacial sediments of Formation 3 and distribution on the courses of the major ice streams together suggest that Formation 2 was deposited in close association with ice. In spite of the firmness of the sediment and the presence of gravel grade material, the consistently distinctive marine dinoflagellate cyst assemblages indicate that this formation comprises marine sediment and not till. The nature of the 'till' in borehole 72/12 is not understood; it may be a submarine 'flow till'⁵ rather than a true till.

Formation 3. A pilot study of this formation in borehole 71/9 shows that the sediments are poorly sorted sandy muds³ similar to Formation 2. They are, however, softer and contain medium sand to pebble grade fragments only rarely, and then at levels coinciding with cold water faunal assemblages.

Study of foraminifera and dinoflagellate cysts has shown that the Formation 3 sequence can be divided into three palaeoclimatic zones¹. From -30 m to -28 m the foraminiferal population is dominated by *Ammonia batavus* (Hofker), a warm, shallow water species. A rich assemblage of dinoflagellate cysts indicates a similar environment. Between -26 m and -16 m a cold water assemblage of foraminifera,

dominated by *Elphidium clavatum* Cushman, coincides with poor recovery of dinoflagellate cysts. From -14 m upwards cold water foraminifera decline in importance. The dinoflagellate cysts from -10 m to the surface are modern in aspect.

The disseminated organic matter contains significant amounts of reworked Mesozoic material. The least contaminated sample was at -6 m; of the organic-walled microplankton only 14.7% were Mesozoic forms and amorphous organic matter appeared fresh. A date of $9,961 \pm 250$ BP was obtained from the disseminated organic matter at this depth (Scottish Reactor Research Centre 117). This has been taken as a maximum age which reduces to 8,680 BP on the assumption that 14.7% of the carbon is old. Assuming continuous deposition it suggests that the older 'warm' water fauna belongs to the Allerød interstadial, the 'cold' water fauna to the period of the Loch Lomond readvance stage and the younger 'warm' water fauna to the final climatic amelioration.

Formation 3 sediments are considered to have been deposited at some distance from the ice front (compare with the 'periglacial marine' sediments of southern Alaska⁷). During deposition of the sequence in borehole 71/9, ice, when present, lay behind the present coastline; a plentiful supply of sediment could be expected both from marine erosion of the sea floor and coastline and from fluvio-glacial sources. This would account for the high sedimentation rate implied by the date. A similar succession has been described on the east coast of Scotland (J. D. Peacock, to be published).

The poor recovery of dinoflagellate cysts between -26 m and -16 m may be attributed to a continuously high level of suspended matter (produced by the Loch Lomond readvance stage) and not to low water temperature. The sus-

pended matter would adversely affect the thecate dinoflagellate population and add a dilution factor resulting from high sedimentation rates⁸. In contrast the significant populations of Formation 2 are inferred to have lived in clear, cold water adjacent to floating ice. Potential suspended matter remained frozen into the ice to be released intermittently, perhaps by seasonal melting, to form Formation 2 deposits.

Formation 4. These sediments form a thin layer (0.05 m to 2.0 m) on all older formations. Their character can be related to bathymetry and situation with respect to the prevailing south-westerly swell. They are interpreted as modern sediments.

Calibration of shallow seismic profiles by the boreholes suggests that Formations 2 and 3 each produce a characteristic seismic texture which can be used to determine their distribution. Formation 3 typically has closely spaced, horizontal reflectors (Fig. 3) which fade laterally and which cannot be correlated with any visible structure in the boreholes. A second characteristic texture, interpreted as Formation 2, has widely spaced reflectors (Fig. 3). Only borehole 72/12 has passed through this unit but if the interpretation is correct then most of the thick sediments west of Colonsay are of Formation 2, as are those in the trench northwest of Coll (Figs. 1 and 3).

West of Colonsay Formation 3 sediments fill shallow depressions on the surface of Formation 2. In contrast, east of Colonsay, in an area protected from the prevailing south-westerly swell, nearly 30 m of Formation 3 sediments have been deposited and preserved at a topographically higher level (compare boreholes 71/9 and 72/12, Fig. 2). Formation 3 sediments also occur in the trench north-west of Coll (Fig. 3) and in the glacial trenches around the Inner Hebridean islands. Considerable variations in their thickness, however, suggest deposition (or subsequent erosion) under the control of a complex system of currents.

On the outer continental shelf the sea floor is relatively flat but the rockhead reflection drops evenly westwards¹. There are no trenches overdeepened by glacial action on rockhead and so the possibility that Tertiary sediments lie above it cannot be excluded.

The two seismic textures on profiles west of Colonsay are also present here. Short (0.8 m) cores taken at the outcrop of the lower unit penetrated a thin (0.1 to 0.5 m) cover of Formation 1 sands and gravels to recover Formation 2 sediments.

Evidence from the land shows that a major ice sheet originating on the mainland moved westwards to extend across the outer shelf. In contrast to this evidence, overdeepened trenches off shore trend along north-east to south-west structures¹. It has been inferred¹ that initially the area was in-

vaded by south-westerly moving ice streams from local high ground, but that during maximum glaciation the westerly moving ice sheet crossed the whole area leaving striae and erratics on areas which are now land. This sequence was reversed during deglaciation.

Deposition of the sediments would have been controlled by the nature of the ice and the manner of its retreat, in particular its relation to changes in sea level. A complex history of sedimentation is thus indicated and the reconnaissance nature of the evidence presented here allows only outline conclusions to be drawn.

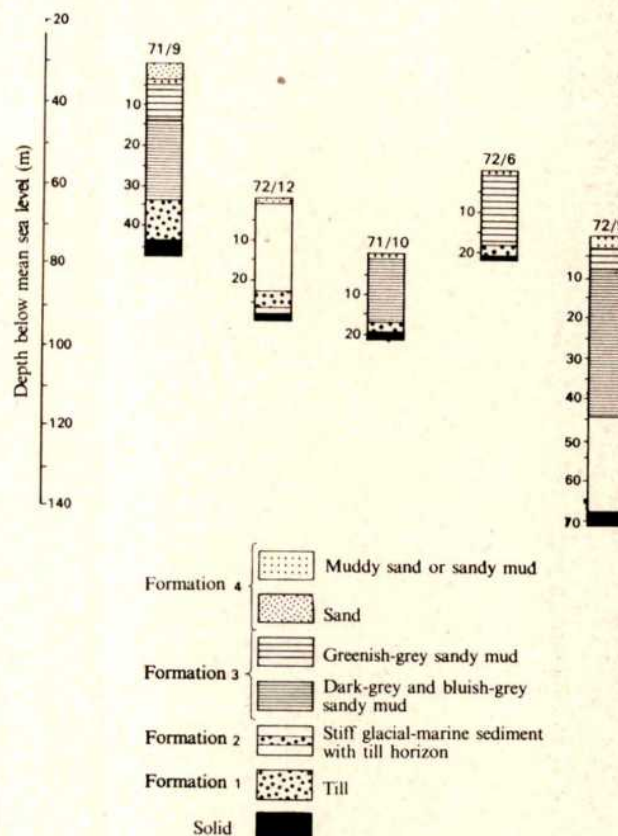

Fig. 2 Boreholes through Quaternary sediment.

It is suggested that the four formations were deposited diachronously by the retreating ice of the last (Devensian) ice sheet. The Formation 2 sediments on the outer continental shelf (Fig. 1) were deposited by the main ice sheet, and those west of Colonsay and north-west of Coll (Figs 1 and 3) by major, south-westerly moving ice streams, probably at a more advanced stage in the retreat. Their thickness reflects

Fig. 3 Shallow seismic sections A-B and C-D. For locations see Fig. 1. Vertical scale in ms, two-way travel times below sea floor. R, rockhead; 1, surface of Formation 1; 2, surface of Formation 2.

the size and activity of the parent glaciers. Formation 3 sediments were deposited at a distance from the ice. When the supply of Formation 3 sediment became exhausted and sea level readjusted to its present position the deposits of Formation 4 were formed.

This study is being undertaken as part of the research programme of the Institute of Geological Sciences.

Carbon fibres with large breaking strain

It has been predicted¹ that carbon fibre with a Young's modulus near 200 GN m⁻² could be prepared from acrylic precursors to yield elastic breaking strains of 2 to 3% with the proviso that an internally clean precursor was selected, judiciously processed and then surface treated to remove the more serious surface flaws. The prediction was made on the basis of gross internal and surface flaws controlling the strength characteristics of acrylic-based carbon fibres, at least in the region of carbonisation temperatures 1,000 to 1,300° C and in the associated modulus range 140 to 240 GN m⁻².

Fibres with such properties have now been prepared in experimental quantities. The breaking strain of carbonised (1,000° C) acrylics with no subsequent surface treatment is limited to about 1.0% in the modulus range 140 to 210 GN

TABLE 1 Single fibre properties of as-processed fibre; gauge length 23 mm

Cross-sectional area (10 ⁻¹² m ²)		Strength, (GN m ⁻²)		Young's modulus (GN m ⁻²)		Breaking strain (%)	
Mean	s.d.	Mean	s.d.	Mean	s.d.	Mean	s.d.
48.1	5.9	3.17	0.30	207	10	1.53	0.20

m⁻² (ref. 2) and fibre processed to much higher temperatures inevitably yields lower breaking strain^{3,4}. Apart from an isolated report of a few ultra-high strength carbon fibres from Japan⁵, commercial fibres are being offered⁶ which have been surface-treated to give mean breaking strains just above 1.3%.

The acrylic previously shown to have a low internal flaw concentration of 10 flaws per metre (ref. 1) was processed through a batch oxidation, continuous carbonisation route to 1,100° C. The resultant fibre had single fibre properties quoted in Table 1.

TABLE 2 Frequency of fracture initiation by internal flaws¹².

Gauge length (mm)	Internal flaw fracture frequency $F_{int}/(F_{int} + F_{sur})$	Precursor internal flaw prediction $(1 - P)$
10	0.13	0.11
23	0.31	0.33
50	0.30	0.45

Because of the excellent control of processing parameters during preparation the Young's modulus was acceptable and the breaking strain already high. These fibres were submitted to an improvement of previously used surface treatments^{1,3,7,8} to modify the surface flaws normally operating. Treated fibres were then tested in tension by a rigorously controlled testing technique at gauge lengths of 10, 23 and 50 mm; at least 25 fibres were randomly selected for each gauge length. In addition a microscopic loop test⁹⁻¹¹ was carried out to estimate breaking strain at the very short effective gauge length of 0.1 mm. Because the loop test is particularly insensitive to well-spaced but severe flaws it provides some idea of the intrinsic breaking strain between severe stress-raising discontinuities.

Cross-sectional areas of the dog-bone-shaped fibres (Fig. 1) were determined by planimeter measurement of photographic enlargements of collected fractured ends at $\times 2,500$. This

FIG. 1 Fracture surfaces of fibres with high breaking strain broken in tension ($L_g = 50$ mm), showing fracture initiated at: a, modified surface flaw ($\epsilon = 2.21\%$); b, internal flaw ($\epsilon = 1.78\%$); c, residual severe surface flaw ($\epsilon = 1.1\%$).

FIG. 2 Breaking strain distributions for various gauge lengths. a, Loop; b, $L_g = 10$ mm; c, $L_g = 23$ mm; d, $L_g = 50$ mm.

method has been cross checked for round fibres against normal optical measurement of fibre diameter. Although the probable error is still large at $\pm 7\%$, at least the area is determined at the point of fracture so it is likely to be more correct for fibre strength than for modulus (for which a mean cross-sectional area along the gauge length is required). The Young's modulus value has been verified by alternatively testing the fibres in an epoxide resin composite using standard composite techniques. Breaking strain determinations however, remain independent of fibre cross-sectional area and are favoured in the present discussion. Since the fibres behave essentially elastically to the point of failure, values of breaking strain adequately reflect the strength characteristics.

Examination of fractured ends of fibre, previously carried out by scanning electron microscopy^{1,3,7,12}, was carried out by high quality optical microscopy. The fracture pattern invariably indicated the fracture initiation source (Fig. 1). From fractography studies the frequency of fracture initiation by internal flaws¹ could be elucidated as well as breaking strain distribution associated with those internal flaws.

Breaking strain distribution data are given in Fig. 2 for various gauge lengths. There is a strong gauge length effect but mean breaking strains in excess of 2.0% are achieved at

gauge lengths less than 23 mm. Such strains will, it is believed, become operative in normal tensile loading of well bonded CFRP composites. It is also strikingly obvious that there has been a significant increase in the loop breaking strain ($\bar{\epsilon} = 4.9\%$) over the previously reported values of $\epsilon = 2.8\%$ (ref. 1) and $\bar{\epsilon} = 3.2\%$ (ref. 11). A typical loop at an apparent strain of 5.0% is shown in Fig. 3. At these high strains the loop was slightly distorted into a spiral. This can provide a significant underestimation of loop diameter in normal microscopic observation, correction for which was made by additionally measuring the height difference between sides of the loop at the point where loop diameter is measured.

Spiral distortion also introduces a deviation from elastica behaviour and $\epsilon = r/R$ (ref. 11); the loop strains are probably overestimated therefore but it can be safely assumed they are well in excess of 3.0%. This conclusion is supported by the significantly high proportion (33%) of fibres which had breaking strains in excess of 3.0% in the tensile tests at 10 mm gauge length (Fig. 2).

In normal tensile tests of this and other samples from the same acrylic precursor a significant number of fractures were initiated at internal flaws to provide the distribution of Fig. 4. These data were not available in previous studies¹ to adequately predict the gauge length effect of internal flaws. It was previously assumed that when internal flaws caused

FIG. 3 Fibre sustaining a strain of 5.0% in loop test.

fracture the strength would be reduced on average to 0.33 of the intrinsic strength between flaws (loop test). It can now be seen for this particular acrylic-based fibre that the internal flaws are not very severe and operate in a comparatively narrow distribution about a mean breaking strain of 1.71% (mean strength 3.5 GN m^{-2}). If these internal flaws

FIG. 4 Breaking strain distribution associated with fractures initiated at internal flaws.

Fig. 5 Predicted (a) and experimental (b) mean breaking strain as functions of gauge length. Breaking strain standard errors are 0.13, 0.14, 0.06 and 0.07 for the four points on the curve in order of decreasing breaking strain.

are permitted to operate fully, then the gauge length effect can be predicted from their distribution in the original precursor acrylic¹ using

$$\epsilon = \epsilon_1 P + \epsilon_2 (1 - P)$$

where $\epsilon_1 = 4.9\%$ (loop tests), $\epsilon_2 = 1.71\%$ (Fig. 4) and P is the probability of avoiding an internal flaw for the particular gauge length^{1,13}. This is shown in Fig. 5, with the present experimental results. In spite of the improved breaking strains now achieved there is apparently a significant potential still to be tapped, even allowing for overestimation of loop breaking strain. The present shortfall in experimental values of breaking strain is partly explained by the persistence of some surface flaws causing fracture at low strain values, as indicated by the low strain tails of the distributions of Fig. 2. An example of such a fracture is illustrated in Fig. 1c. These particular surface flaws must be fairly well spaced at 50 to 100 mm and obviously contribute to the strong gauge length effect of Figs 2 and 5. In addition, they restrict the full operation of internal flaws, particularly at the longer gauge lengths. This is verified by the fracture frequency results of Table 2 where reasonable agreement between experimental and predicted frequencies is seen to extend only up to gauge lengths of 23 mm.

In addition to the achievement of breaking strains in excess of 2.0% at acceptable gauge lengths, the persistent operation of gross flaw mechanisms of fracture has been clearly demonstrated. There is no serious conflict between this treatment and the recent prediction of strength being dependent on ribbon wrinkling in graphitised fibre¹⁴. It has been recognised that structural features in addition to gross flaws may become progressively operative in controlling fracture in carbon fibre processed to graphitisation temperatures.

These studies confirm the earlier prediction on the feasibility of high breaking strain (2 to 3%) carbon fibres¹. They also form a satisfactory technical conclusion to the coherent and consistent treatment^{1,3,7,11-13} of carbon fibre strength and breaking strain on the basis of gross flaw mechanisms of brittle fracture applying at least to acrylic-based fibres processed to the carbonised stage. There remains scope for further development with the improvement of surface treatment techniques. The intrinsic breaking strain looks promisingly high, well in excess of 3.0%, and the strength correspondingly well above 6.0 GN m⁻² (0.9×10^6 pound inch⁻²).

I thank colleagues at Fibre Research for help and Mrs V. J. Coffey for testing.

Crystal structure of polyvinyl alcohol

THE first comprehensive X-ray analysis of polyvinyl alcohol (PVOH) showed that the thirty observed reflections could be indexed according to a pseudo-orthorhombic cell¹. Bunn² later proposed a monoclinic unit cell comprising two molecules lattice parameters: $a = 7.81 \text{ \AA}$; $b = 2.52 \text{ \AA}$; $c = 5.51 \text{ \AA}$; $\beta = 91^\circ 42'$.

It was thought that the periodicity of 2.52 \AA must imply an isotactic configuration with hydroxyl groups in identical positions along the backbone chain. This rather unlikely

Fig. 1 X-ray diffraction photograph of crystalline PVOH fibre. 2θ for the 004 reflection is $33^\circ 40'$.

FIG. 2 X-ray diffraction photograph showing both crystal forms. 2θ for the 004 reflection is $33^\circ 40'$.

structure was modified by Bunn, who postulated that the repeat distance of 2.52 \AA was "equally compatible with a molecular structure in which hydroxyl groups are randomly placed in left and right-handed positions".

Despite several later analyses³⁻⁵ the same basic lattice parameters and molecular configuration are widely accepted today. Mochizuki⁵ quoted a slightly higher fibre identity period of 2.533 \AA which he obtained from a tilted-fibre photograph and, in agreement with Bunn, he considered PVOH to have a planar zigzag configuration. From an azimuthal scan of the so-called 100, 200 and 101 reflections, he found that as well as a maximum on the equator of the diffraction pattern, there was another at about 30° from the meridional axis. He therefore postulated that not all of the crystallites in an oriented fibre tend to arrange themselves with their long axis parallel to the fibre axis. Some are tilted by a very considerable angle (about 60°) to the direction of draw. No possible reason was given for this.

One of the most interesting problems encountered in the X-ray analysis of PVOH concerns the molecular conformation of stereoregular polymer. Both syndiotactic-rich and isotactic-rich PVOH have been prepared from the corresponding formate⁶. It is rather surprising, however, that no essential differences were noticed between their X-ray diffraction patterns—each showed an identity period of 2.5 \AA .

I have found that the crystal structure of PVOH is somewhat more complex than has been previously realised. I used a commercial PVOH (Elvanol 71-30) to prepare highly drawn fibres because the chemical characteristics are advantageous for fibre production⁷. The more important qualities include a very high degree of hydrolysis (99%–99.8%), a suitable molecular weight (80,000) and a maximum ash content of 1%. A 20% aqueous solution of this polymer was extruded into a coagulation bath containing concentrated ammonium sulphate solution. No appreciable tension was applied at this

TABLE 1 Lattice parameters of the two crystal structures of PVOH

α form (monoclinic)	β form (orthorhombic)

stage. After complete coagulation, a wet-drawing stage was incorporated in order to impart a degree of orientation sufficient to prevent dissolution of the fibres at the washing stage. After being collected and dried, the product was hot-drawn over a plate maintained at 200°C . Cylindrical and flat-film X-ray diffraction photographs were taken, using nickel-filtered $\text{CuK}\alpha$ radiation with exposure times from 1.5 to 4 h. Finely powdered copper was used as an internal standard, and the spacing of 2.088 \AA was chosen as the reference line (American Society for Testing Materials, Powder Data File No. 4-0836).

X-ray diffraction photographs show many more reflections than have been previously noticed (Fig. 1). Of particular importance are those lying between the equator and the meridian, because they immediately indicate the existence of a somewhat larger unit cell than has been previously recognised. A detailed study of the diffraction pattern shows that no single unit cell can adequately account for all of the observed reflections. A system embodying two crystal structures will, however, account for them very satisfactorily. I therefore propose that polyvinyl alcohol crystallises in two forms which have the lattice parameters presented in Table 1. Tables 2 and 3 compare the observed and calculated values of $\sin^2 \theta$ based on these cells. The agreement is very good. Calculated density values agree with observed values for highly crystalline fibres. Assuming 18 monomers per orthorhombic unit cell, a density of 1.322 g cm^{-3} is obtained. For the monoclinic system, a density of 1.400 g cm^{-3} is obtained, assuming 24 monomers per cell.

Generally speaking, reflections belonging to the orthorhombic system are weak in intensity, presumably as a result of a structural preference for the monoclinic system. By altering both the total draw ratio and the temperature of the hotplate, fibre samples having varying proportions of the two crystal structures can be prepared. Figure 2, for ex-

Fig. 3 X-ray diffraction photograph showing the monoclinic form only. 2θ for the 004 reflection is $33^\circ 40'$.

ample, shows reflections of up to 35° (2θ values) and exhibits both crystal forms. On the other hand, Fig. 3, consists only of reflections from the structure rich in the monoclinic form. Although the precise configuration of the polymer chains within the crystalline regions is unresolved at present, the fibre periodicities suggest a twisted or helical structure for both crystal forms. The monoclinic system, with a periodicity of 7.59 Å, may be explained in two ways. It is possible that the polymer exists as a kinked chain in which every third hydroxyl group is in an equivalent position. Alternatively, if there is a high degree of syndiotacticity, a structure incorporating four monomer units per fibre repeat may be present. This latter type of configuration has been claimed for syndiotactic polypropylene⁸ and has been suggested for polyacry-

Fig. 4 Effect of water on the diffraction pattern of PVOH. 2θ for the 004 reflection is $33^\circ 40'$.

lonitrile (B. G. Colvin, and P. Storr, not yet published). These polymers have identity periods of 7.4 Å and 7.1 Å respectively. Furthermore, it is well known that the infra-red spectrum of PVOH shows a fairly high absorbance at 916 cm^{-1} , a wave number usually associated with the syndiotactic form. I feel, however, that the former proposal is in fact the more likely, because the 030 and 060 reflections are relatively strong and the 020 and 040 reflections are not visible at all (Table 1). It therefore seems that crystalline PVOH consists of a kinked chain with three monomers per repeat. The distortion of the main chain is regular and is apparently governed by a combination of mutual repulsion between neighbouring hydroxyl groups and a complex hydrogen-bonding mechanism.

It is reasonable to suppose that stereoregular PVOH may be examined more successfully provided that polymer samples of high crystalline order can be obtained. The following parameters are found to have a pronounced effect on the amount of detail manifested in a wide-angle X-ray diffraction pattern. First, the degree of jet-stretch is of some importance. This should be kept to a minimum, as it has been observed that a higher crystalline order is obtained by allowing the fibre to relax as much as possible in the coagulation bath. Second, a high degree of orientation is of the utmost importance, and this should be imparted principally at the wet-drawing stage. Third, dilute solutions of coagulant salts should be avoided as much as is practically possible. Water molecules adversely effect the naturally occurring hydrogen-bonding mechanism which is responsible for high degrees of order (Fig. 4), and washing stages should therefore be kept to a minimum. Even after crystallisation has occurred to a very high degree (Fig. 1), water molecules can penetrate the crystalline regions and thus modify the molecular packing arrangement. The only noticeable periodicity in the fibre direction after such treatment, results from the chemical repeat of 2.5 Å. Presumably the kinked chain is no longer regular as a result of the disruption of hydrogen bonds within the polymer network. Crystallisation can still occur, however, but to a much lesser degree. The small size of the hydroxyl group is probably the reason that PVOH can crystallise at all under these conditions². Whether there is any marked variation in the lateral packing of chains is uncertain at present, although no pronounced variations in the equatorial reflections have been noticed. It is proposed that more information may become available from fibres of varying tacticity produced in the near absence of water. The use of organic precipitating baths may prove useful in this respect.

This analysis also suggests that there is now no real evidence to support a 'preferred tilted-crystal orientation' theory, because an azimuthal scan of the so-called 100, 200 and 101 reflections would necessarily give rise to other maxima. These, however, arise from quite separate reflections, namely the 012 or 310 of the monoclinic system and the 211 of the

orthorhombic cell. It must be presumed that Mochizuki⁵ had prepared a sample of PVOH showing some signs of increased crystalline order but, instead of assigning separate indices to the off-equatorial maxima, he included them as part of the equatorial arcs.

I thank Mr E. Segerman for help, and Professor H. Lipson and Dr C. W. Bunn for discussions.

Estimation of solubility parameters of nonelectrolytes

THE Hildebrand approach^{1,2} provides an explanation of the solubility of nonelectrolytes based on a thermodynamic method. In this method used for the estimation of solubility, it is assumed that each molecule possesses a characteristic potential energy based on intermolecular forces which may be described as the cohesive energy density. The latter may be defined as the potential energy of 1 cm³ of liquid or the energy required to separate all molecules in a unit volume of liquid. This value is zero when the molecules are randomly dispersed in a solution.

The solution process may be compared with the vaporisation process in which molecules at an equilibrium distance are transported to an infinite distance. Accordingly, the energy of vaporisation is used to quantify the solution process in the Hildebrand approach. Thus, the solubility parameter which is represented by the symbol δ is equal to the square root of the cohesive energy density (CED). The latter is equal to $\Delta E_v/V$ in which ΔE_v is the energy of vaporisation and V is the molar volume.

As shown by the following equations, values for the solubility parameter (δ) which is the square root of CED, may be calculated from the heat of vaporisation per mole (ΔH_v), the gas constant (R), the temperature on the Kelvin scale (T) and the molar volume (V):

$$\begin{aligned}\delta &= (\text{CED})^{1/2} = \left(\frac{\Delta E_v}{V}\right)^{1/2} = \left(\frac{\Delta H_v - RT}{V}\right)^{1/2} \\ &= \left(\frac{\Delta H_v - RT}{M/D}\right)^{1/2} = \left(\frac{D(\Delta H_v - RT)}{M}\right)^{1/2}\end{aligned}$$

The above equation is derived from the following relationships:

$$\Delta H_v = \Delta E_v + P\Delta V = \Delta E_v + RT \therefore \Delta E_v = \Delta H_v - RT$$

$$D = M/V \therefore V = M/D$$

Because of the difficulty in obtaining values for the molar volume, the quotient of the gram formula weight (M) and density (D) is substituted for the value V . The units for δ values obtained from the preceding equation are (calorie cm⁻³)^{1/2} but the term hildebrand has been adopted in some instances for this unit³. According to the solubility parameter concept, solubility occurs when the δ values of solid solute and a liquid solvent are within a range of 2 hildebrands (2 H).

The quality of hydrocarbon solvents such as benzene, cyclohexane or hexane is readily described by δ values and these nonpolar solvents are called regular solvents. But the potential energy of solvents increases with polarity because of additional interactions resulting from dipole-dipole (Keesom) forces, induced dipole-dipole (Debye) forces and acid-base type (Lewis) forces and provisions must be made to account for these additional interactions in applications of the solubility parameter concept. Burrell⁴ has classified solvents as poor, moderately bonded and strongly bonded solvents.

Several graphical approaches have been suggested for the estimation of δ values. Values of ΔH at 298 K may be estimated from the boiling points (T_b) and these values may be used for the calculation of δ values by use of the following equation⁴:

$$\Delta H_{298} = 23.7T_b + 0.02T_b^2 - 2,950$$

(see Fig. 1).

It has also been shown previously⁵ that the contribution of the methylene group (CH₂) to the δ values is constant⁵ and so the δ values for solvents in a homologous series may be estimated from the graph shown in Fig. 2 (ref. 6).

The logarithm of δ values of nonpolar solvents such as hexane ($\delta = 7.3$), cyclohexane ($\delta = 8.2$) and benzene ($\delta = 9.2$) are related to readily obtainable physical constants as shown by the following equation and by line A in Fig. 3;

$$\log \delta \simeq 0.50 \log \frac{T_b D}{M} + 0.655$$

Fig. 1 Relationship of ΔE_v and boiling point.

Fig. 2 Relationship of solubility parameters and carbon numbers in various homologous series of solvents. A, Normal alkanes; B, normal chloroalkanes; C, methyl esters; D, alkyl formates and acetates; E, methyl ketones; F, alkyl nitriles; G, normal alkanols; H, alkyl benzenes; I, dialkyl phthalates.

A slightly different equation may be used to estimate the logarithm of δ values for moderately bonded solvents as shown below:

$$\log \delta \cong 0.40 \log \frac{T_b D}{M} + 0.665$$

These values which apply for solvents such as ethyl ether ($\delta = 7.4$), butyl acetate ($\delta = 8.0$), acetone ($\delta = 9.9$) and dimethyl sulphoxide ($\delta = 12.0$) are shown as line B in Fig. 3.

The logarithm of δ values of strongly hydrogen bonded solvents may be estimated from line C in Fig. 3 or from:

$$\log \delta \cong 0.40 \log \frac{T_b D}{M}$$

Fig. 3 Relationship of $\log \delta$ and \log of readily available constants.

Typical strongly hydrogen bonded solvents are diethylamine ($\delta = 8.0$), sec. amyl alcohol ($\delta = 10.0$), acetic acid ($\delta = 10.1$), and aniline ($\delta = 10.3$). Because they exist primarily as dimers, the M values used for formic and acetic acids are twice the molecular weights of the simple molecules.

The logarithm of δ values of solids such as naphthalene ($\delta = 9.9$), β -bromonaphthalene ($\delta = 10.6$) and maleic anhydride ($\delta = 13.6$) may be estimated from line D in Fig. 3 and from:

$$\log \delta \cong 0.50 \log \frac{T_m D}{M} + 0.670$$

Tables of solubility parameter values are readily available⁴. As shown by the following example, solubility parameters may also be readily calculated from the graphs included in this report. The boiling point of carbon tetrachloride is 77°C or 350 K. According to Fig. 1, the value of ΔE for carbon tetrachloride is 7.2 kcal/mol. Therefore, by use of the relationship

$$\delta = \left(\frac{\Delta E}{V} \right)^{1/2} = \left(\frac{D(\Delta E)}{M} \right)^{1/2} = \left(\frac{7,200(1.6)}{154} \right)^{1/2}$$

one obtains a δ value of about 8.4 H for carbon tetrachloride.

Similarly, according to line H in Fig. 2, the δ value for toluene ($C = 7$) would be about 8.9. The scale for the ordinate is an arbitrary one chosen so that linear relationships could be demonstrated when the number of carbon atoms in the solvent was plotted against the solubility parameter values in hildebrand units. The δ value of a strongly hydrogen bonded solvent such as methanol may be estimated from line C in Fig. 3 by using the values $T_b = 338$ K, $D = 0.79$ g/cm³, $M = 32$. So

$$\log \frac{T_b D}{M} = 0.922$$

Thus, $\log \delta = 1.16$ and $\delta = 14.5$ H.

In addition to providing quantitative values in place of the qualitative expression, 'like dissolves like,' the solubility parameter may be used to explain that while cellulose nitrate ($\delta = 10.5$ H) is insoluble in either ethanol ($\delta = 12.7$ H) or ethyl ether ($\delta = 7.94$), it is readily soluble in an equimolar mixture of these two solvents ($\delta = 10.0$ H). This solution, called collodion or newskin, is still in use today.

The solubility parameter may also be used to explain many well known unique solvent systems such as a saturated aqueous solution of urea. This solution of natural origin has been used to dissolve dried blood, to soften animal skins, to set hair, to disperse the ingredients of gun powder, to aid the inking of lithographic plates, to make wood flexible and to improve the flow of cold house paints.

Applications of Boolean programming optimisation methodology to the direct solution of crystal structures

We have found that Boolean optimisation methods can be used to derive phase information from observed X-ray structure factors. This will provide a new approach to the problem of the loss of phase information during X-ray diffraction experiments, which has been a major limitation to the study of the structure of matter. The possibilities of the method are demonstrated here in the successful application of integer programming optimisation techniques to the three-dimensional solution of centrosymmetric structures.

Current direct methods¹⁻⁵ involve statistical relationships among a group of reflexions preselected to be strongly influenced by the atomic arrangement. The phase problem assumes two levels of complexity depending on (1) the absence or (2) the presence of a centre of symmetry. (1) In the more complex general case, the phase angle is free to assume all values from 0° to 360°. (2) The presence of a crystallographic centre of symmetry constrains the phase angle to 0° or 180°, and the cosine of the phase angle is therefore constrained to ± 1 .

The phase relationships can be formulated in terms of classical integer programming. For the centrosymmetric case, the variable, X , equal to zero or one, corresponds to a sign or $-$ or $+$ (for example, $\text{sign} = -(-1)^X$). Freeman⁶ and Dakin⁷ have explored the use of integer programming techniques in the one-dimensional case, and Lesk⁸ redetermined the planar structure of dihydrouacil in a two-dimensional integer programming formulation. We now report the application of integer programming techniques in three dimensions to the solution of the hitherto unstudied molecule, spiro-[5.5]-undeca-1,4,7,10-tetraene-3,9-dione⁹, 'spirodienone'. We have also redetermined the structure of potassium lead hexanitrate(II), $\text{K}_2\text{PbCu}(\text{NO}_3)_6$, using the structure factors of Cullen and Lingafelter¹⁰.

We have found that certain integer programming methods fail when identical constraints are used. Therefore, a disjoint set of inequality constraints was chosen to place upper and lower bounds on the values of electron density at points in the crystallographic unit cell. For the spirodienone study, choice of these points was assisted by a procedure similar to the application of the symmetry minimum function to Patterson(vector) space¹¹. Pronounced valleys are located on the map of the Patterson function and a valley in vector space is related to positions in real space where no atom is expected to appear. For the centrosymmetric case, a point of minimum density in vector space at $2x, 2y, 2z$ can be mapped into real space at x, y, z , together with the related points within the unit cell generated by symmetry and translations. For space group $\text{P}\bar{1}$, points need to be mapped into only half the unit cell, which is the asymmetric unit. In higher symmetry space groups, the location of local minima in Harker lines and sections would help establish positions in real space for the assignment of constraints.

A typical constraint in space group $\text{P}\bar{1}$ can be constructed by setting bounds to the inequalities:

$$\sum_{j=1}^n A_{ij}X_j - b_i \leq \text{upper bound and}$$

$$\sum_{j=1}^n A_{ij}X_j - b_i \geq \text{lower bound.}$$

The index, i , refers to a point in real space; j refers to a reflexion. The variable X_j assumes binary values zero or one as the phase of reflexion j is assigned a value of 180° or 0°. The coefficient A_{ij} represents twice the value of the computed electron density at point i from structure factor j , (assuming a positive sign for each F value) that is $A_{ij} = (4/V) |F_j| \cos 2\pi(h_jx_i + k_jy_i + l_jz_i)$, where V is the volume of the unit cell. The term b_i is evaluated to be half the sum of all the terms A_{ij} at point i for n reflexions: that is, $b_i = 1/2 \sum_{j=1}^n A_{ij}$. The upper and lower bounds are

near-zero-valued parameters which define a window within the computed electron density summation must fit. The assignment of a value of one to phasing term X_j has the net effect of adjusting the electron density by the contribution of the positive structure factor j at that point. Conversely, if X_j is equal to zero, the effect is to adjust the contribution of reflexion j to the electron density due to the negative sign.

If the choice of variables X_j corresponded with the correct set of signs, the left-hand side of the inequality constraints would approximate the actual electron density at each point where the constraint is computed. Deviations from the actual electron density may be attributed both to errors inherent in the data set (which would usually be minimal) as well as to the incomplete nature of the data set due to limitations in computer size. When the objective function and a set of constraints are input to the surrogate constraint Zero-One Algorithm¹² then all feasible sets of phases which are found on the way to the optimum solution are output. For spirodienone, the coefficients in the objective function were biased by the computed value of the electron density due to each reflexion in the Fourier summation at the starting position. Then optimisation techniques 'tour' solution space in search of the optimum phases.

For the first trial of the method we chose spirodienone because of its structural interests to spectroscopists and its suitability for our procedure. Crystals of spirodienone, $\text{C}_{11}\text{H}_8\text{O}_2$, were grown from a dioxane solution of pure compound provided by Dr Guy Farges. Cell parameters are:

$$\begin{array}{lll} a = 9.08 \text{ \AA} & b = 13.61 \text{ \AA} & c = 7.49 \text{ \AA} \\ \alpha = 91.11^\circ & \beta = 96.91^\circ & \gamma = 100.50^\circ \end{array}$$

$\text{P}\bar{1}$, $Z = 4$. Thus there are two independent molecules of 13 non-hydrogen atoms in the asymmetric unit. The diffractometer data were reduced to normalised structure factors (E values). An analysis of the E values showed the presence of a strong subcell, therefore the structure was first solved by a direct methods program, MULTAN⁵, to establish that a solution would be forthcoming.

The method worked well when it was provided with the starting position of a single atom (taken from a peak of the MULTAN E map) to define the origin of the unit cell. The coefficients in the objective function were biased by the computed value of electron density due to each reflexion in the Fourier summation at that known position. For 170 variables (signs) and 160 constraints a near optimum solution was found within 80s on a CDC 6600 computer. The resulting 170 signed E values were input to a Fourier program and the resulting E map clearly indicated twenty-three of the twenty-six non-hydrogen peaks. Four cycles of full matrix least squares refinement of the twenty-three peaks produced an R factor of 30.0% (based on F) and a new set of signs that, in the next Fourier calculation, yielded the remaining three atoms. All non-hydrogen atoms together with their isotropic temperature factors refined to an R factor of 13.9%. Further refinement has lowered R to 4.8%.

We were not satisfied that *a priori* information would be a necessary condition for the proper functioning of the

optimisation approach. We therefore redetermined a known structure, this time in the cubic crystal class, with several heavy atoms (Pb, K, Cu) as well as light atoms (N, O) in the molecule. Potassium lead hexanitrocuprate (II) crystallises in space group $Fm\bar{3}$, $a_0 = 10.672\text{\AA}$.

Normalised structure factors were generated from the observed reflexions. The statistical distribution of the E values was highly uncharacteristic for both centric and acentric cases. The highest E was only 1.85. The application of the optimisation approach produced the correct structure in a straightforward manner.

The fifteen atomic parameters were sought by applying ninety lower-bound constraints on electron density. All points were chosen from an 0.5\AA grid in the asymmetric unit without reference to the Patterson map, as in the first structure. Fifty structure factors corresponding to the highest thirty-five E values in the parity group *ggg* and the highest fifteen in the other parity group, *uuu*, were used. The signs thus determined were used in a Fourier summation which yielded the correct structure. This second solution thus demonstrates that Boolean optimisation methods can derive phase information directly from the observed structure factors without *a priori* information. As these two analyses are our first two attempts to test the strengths and limitations of this approach, the results are encouraging. However, more study is required to define the critical parameters of the constraint's expression and the limitations of the method itself.

In conclusion, two analyses of the phase problem in the centrosymmetric case have been made. In the first trial, one atom at a known position was required to bring about phasing convergence. Although as mentioned, *a priori* information was required, this trial suggests the possibilities of this method for phase refinement or phase extension. As a second trial we chose a molecule in the cubic class. The method was able to proceed directly from structure factors to signs without *a priori* assumptions or information. Thus, a nonstatistical approach to direct methods is possible by means of Boolean programming optimisation methods.

We thank Professor A. Dreiding and Dr G. Farges for spirodienone and the staff of the CSCF at Brookhaven National Laboratory for computational assistance, as well as the staff of the Department of Chemistry at Brookhaven for hospitality, and Dr Larry Andrews for critical suggestions. We also thank Drs David Cullen and Arthur Lesk for advice and helpful discussion. This work was carried out by one of us (D.G.K.) in partial fulfillment of the PhD degree at Texas A and M University and was supported by a grant from the US National Science Foundation.

BIOLOGICAL SCIENCES

Premature ageing and occurrence of altered enzyme in Werner's syndrome fibroblasts

HUMAN diploid fibroblasts cannot be propagated indefinitely in culture¹. Longevity experiments with fibroblasts grown from skin biopsies from individuals of different age show that the greater the age of the donor, the shorter the lifespan of their cells in culture²⁻⁴. Patients suffering from Werner's syndrome age prematurely and have an average lifespan of 46 yr (ref. 5). Martin, Epstein and Sprague⁴ established primary fibroblast cultures from skin specimens from four such patients and discovered that these could be subcultured only 4-11 times before growth ceased. This compares with an average lifespan of 32 subcultures for skin fibroblasts from normal individuals in the same decades of life⁴. We show here that changes which occur in the enzyme glucose-6-phosphate dehydrogenase (G6PD) during the senescence of normal fibroblasts⁶, also occur during the premature senescence of cells from a patient with Werner's syndrome.

Werner's syndrome is an inherited condition, caused by a rare autosomal recessive allele⁵. A review and critical appraisal of the similarities between normal ageing and premature ageing in these patients is available⁵. The features of Werner's syndrome are first seen soon after adolescence. Normal development is then interrupted by greying of the hair and sometimes baldness, impairment of further bodily growth, loss of subcutaneous tissue and muscle, and progressive changes in the skin, all of which give the affected individual a prematurely aged appearance. Other changes which typically take place include bilateral cataracts, weakness of the voice and underdevelopment of the genitalia with consequent low level of fertility. Arteriosclerosis becomes manifest and calcium is deposited in arterial walls. The development of mild diabetes is common, and there is also an unusually high incidence of neoplasms. The combination

TABLE 1 Estimates of the heat-labile fraction of G6PD in Werner's syndrome cells, controls and MRC-5 cultures of different age.

Culture	Donor	Passage No.	% Heat-labile enzyme
Werner's skin fibroblasts	Male, age 46	7	21
		9	23
		9	22
		11	22
		11	21
Normal skin	Male, age 54	11	9
		25	8
		27	6
	Female, age 40	8	4
		22	4
Normal MRC-5	Male	10-40	range: 0-10
foetal lung fibroblasts		(27 experiments)	mean: 5.8
Senescent MRC-5	Male	53-68	range: 10-27
		(34 experiments)	mean: 16.7

Each determination is based on an experiment of the type shown in Fig. 1. The summary of results with MRC-5 are taken from Holliday and Tarrant⁶.

FIG. 1 The inactivation by heat of G6PD in a cell-free extract from passage 11 skin fibroblasts, derived from a patient with Werner's syndrome. The methods for the preparation of extracts and the assay of the enzyme are as previously described⁶.

of subcutaneous wasting with taut and shiny skin results in spindly extremities, which contrast with a stocky trunk. Callosities and later ulcers develop on the ankles as well as over the Achilles tendons of the heels. Although these ulcers are particularly indolent and resistant to effective treatment, vascular insufficiency does not seem to be responsible. Their failure to heal probably reflects the limited division potential of cells which normally replace tissue over these areas which are vulnerable to pressure and damage.

Several of these features in a male patient (DD), aged 40, led to the diagnosis of Werner's syndrome in 1966 (ref. 7). In July 1972 specimens of skin and subcutaneous tissue were taken from the forearm and samples were used to establish primary fibroblast cultures. Small pieces of tissue were placed under coverslips in Leighton tubes and incubated at 37° C in Eagle's basal medium containing 10% foetal calf serum and 10% tryptose phosphate broth. Half the medium was changed twice weekly. When sufficient cells had migrated from the tissue and grown to form a monolayer, they were removed after trypsin treatment and subcultured into small glass bottles. In some cases several populations of cells could be collected at intervals of 2-3 weeks from the same Leighton tube. The cells were passaged with a 1:2 split ratio using the standard procedures for fibroblast cultures⁸, although growth of the Werner's cells was considerably slower than with normal fibroblasts. Of the various cultures established, none survived beyond passage 12. This is in agreement with the results obtained by Martin *et al.*⁴.

Sufficient cells were obtained to carry out several experiments with G6PD, but there was insufficient material to examine any other enzyme. It has previously been shown that healthy cultures of foetal lung strain MRC-5 contain on average about 5% of altered G6PD which is heat labile, whereas senescent cultures can obtain up to 27%, with an average of about 17%⁶. Although it is not ruled out that this altered enzyme is produced by post-synthetic modification, the overall evidence indicates that the errors in protein synthesis are responsible for the changes in the enzyme which are seen during ageing⁶. Five experiments were carried out with cell-free extracts from cultures of Werner's cells, and in each case about 20% heat-labile enzyme was detected. One of these experiments is shown in Fig. 1, and the overall results are given in Table 1. The estimate of the proportion of altered G6PD is accurate to within about 3%. We have examined G6PD from cultured fibroblasts from three normal adults. In each case the amount of altered G6PD is in the same range as non-senescent MRC-5 cultures. These results are given in Table 1. A mixture of a cell-free extract from Werner's cells (21% heat-labile enzyme) and an equal amount of control enzyme (9% heat-labile) gave

the expected intermediate level of altered G6PD (16% heat-labile).

Our results with G6PD show that cells from Werner's patients have at least one biochemical defect in common with senescent fibroblasts derived from a normal individual, and this strengthens the view that the early death of Werner's cells in culture is really due to premature ageing, and makes it more likely that there is a direct relationship between *in vivo* and *in vitro* ageing. The results also add weight to the growing evidence that ageing is associated with the production of defective proteins^{8,9-14}, although so far there is little to indicate whether this is a primary cause of ageing or a secondary consequence¹⁵. One possibility is that the altered proteins arise from an ever increasing level of errors in protein synthesis, as originally suggested by Orgel¹⁶. A genetic defect which accelerated this process could be due to a loss of specificity of one of the many enzymes, or ribosomal proteins, which maintain the normal accuracy of protein synthesis. Most mutations of this type, however, would be dominant or partially so. Recessive mutations are frequently associated with the loss of an enzyme activity; therefore, if the recessive genetic defect causing Werner's syndrome is due to a slight change in the accuracy of protein synthesis, one possibility is that an enzyme which modifies bases in tRNA or rRNA is inactive or absent.

We thank Dr Alex Comfort for his encouragement and V. M. McGuire for cultures of normal skin fibroblasts.

Life span of erythrocyte membrane protein

IN most types of cells the protein constituents of the cytoplasm are constantly being degraded and synthesised¹⁻⁶. When the proteins in these cells are labelled with a protein precursor, the label disappears from the protein with first order kinetics. The amount of any protein in the cell then is regulated by the rate of its synthesis and degradation, and recent work indicates the importance of this process as a regulatory mechanism in mammalian cells. In contrast, when haemoglobin, which comprises 90% of the protein of the mature mammalian erythrocyte, is labelled, it does not decay with first order kinetics, but survives for a finite period. It

Fig. 1 Survival curves of ^{51}Cr and ^{125}I -labelled rat erythrocytes *in vivo*. Labelled cells (1 ml) were injected through the tail vein. At various times, blood samples were taken by tail cut and 0.05 ml of blood was collected into a heparinised capillary tube and mixed with 1.0 ml of normal saline. Samples were counted on a Packard gamma spectrometer. Four combinations of isotope were used: \circ , ^{125}I ; \bullet , ^{125}I Cr; Δ , ^{51}Cr I; and ∇ , ^{51}Cr . Each point is an average of data for four rats corrected for the decay of the isotope used.

disappears from the vascular bed when the intact erythrocyte is removed from circulation. Thus, haemoglobin labels provide excellent material for studies of the life span of the red cell.⁷

Membrane proteins also turn over in most animal cells. In the liver, for example, the half life of the plasma membrane proteins is very short¹⁻⁶. Efforts to label the membrane proteins of the erythrocyte and determine whether it survives similarly for the lifetime of the cell have not been completely successful⁸. Using ^{14}C -glucose which is incorporated into glycopospholipids, Krivit⁹, however, found a mean life span for rabbit red cells of 51 to 60d. These values are similar to but shorter than those obtained by labelling haemoglobin in the rabbit¹⁰. We have now labelled rat erythrocytes by a method previously described¹¹⁻¹³ and have studied the survival of their membrane proteins *in vivo*.

Male Sprague Dawley rats (200 \pm 10 g) were fed a regular diet, given water *ad lib* and housed four or five to a cage. Blood was drawn into plastic syringes containing ACD anticoagulant (0.15 ml ml⁻¹ of blood) from rats anaesthetised with ether. The blood was then placed in plastic tubes. The red cells were separated by centrifugation at 750g for 10 min and the serum was removed. For labelling with chromium^{14,15}, packed cells were obtained from 10 ml of blood. Potassium chromate (10A, 1 mg ml⁻¹) was added with stirring. After incubation at 37°C for 40 min, 0.1 ml of 0.1 M sodium ascorbate solution was added. The cells were incubated for a further 10 min and washed three times in isotonic saline.

To label cells with ^{125}I , packed cells were washed free of

plasma protein in isotonic phosphate buffer. The washed cells were then subjected to lactoperoxidase-catalysed iodination as previously described¹¹⁻¹³, centrifuged, washed three times in isotonic saline, suspended in serum and left overnight. Cells were then centrifuged free of the serum, washed twice in isotonic saline and suspended in saline to give a 50% haematocrit. The cells were also double labelled with either ^{125}I and non-radioactive chromium or ^{51}Cr and non-radioactive iodine. In all cases chromium labelling preceded labelling with iodide.

The cells from four groups of rats, consisting of four animals each were labelled with ^{125}I , ^{51}Cr , ^{125}I and non-radioactive chromium, or ^{51}Cr and non-radioactive iodine, as described above. A sample of 1 ml of cells was injected into the tail vein of each animal, and blood samples were obtained at various times thereafter. The amount of label present in the blood of each of the four groups was followed for 1 month.

As much as 25% of the total label rapidly disappeared within the first few hours after injection of cells. However, the rate of decay became more linear after 20h. Figure 1 shows the decay curve for the disappearance of radioactive label, corrected for the half-life of the isotopes used, from the four groups of animals used. The similarity in the rate of decay between ^{51}Cr and ^{125}I suggests that the label in exposed membrane proteins and that of internal components were disappearing in parallel.

Because ^{51}Cr elutes from the red cell it does not provide a simple relationship to the mean red cell life span^{14,15}. Survival times determined by chromium underestimate the mean red cell life span unless corrected. Since the disappearance of membrane label coincided with chromium decay, the data suggested that iodine was also being lost from the cell. To investigate whether any one of the membrane components is involved in a selective loss of an iodine-labelled component, erythrocyte membranes were isolated and polypeptides were separated by sodium dodecyl sulphate (SDS) polyacrylamide gel electrophoresis.

Previous studies has shown that two proteins on the exterior surface of the human erythrocyte are labelled with the lactoperoxidase system¹¹⁻¹³. One has a molecular weight of 90,000 and the other is the major glycoprotein. In the rat, five polypeptides are iodinated. The major component labelled is in the 90,000 dalton class. The minor components have molecular weights of 68,000, 31,000, 18,000 and include an additional component with a low molecular weight, probably 12,000 or smaller.

As Fig. 2 shows, although there was a marked loss of radioactivity, there does not seem to have been a selective loss of any of the components. The minor components disappeared or were not readily detected after 404 h, because of the small amount of iodine originally incorporated.

The data suggest that labelling of the erythrocyte with the lactoperoxidase probe provides a method for the study of red cell survival, but does not offer any distinct advantages over present procedures. The labelling procedure is somewhat more complicated than the use of chromium. The iodine label gives results which indicate that a significant portion of the iodine label is removed from the cell during its life in the vascular system. The reasons for this are not clear. Chromium and other labelling systems label primarily the haemoglobin molecule which does not turn over as do proteins in other cell types, but survives for the life span of the red cell and is lost primarily by removal of the intact cell.

In other types of cells there is a marked difference in the rate of turn over of individual proteins of a membrane system¹⁻⁶. Analysis of the membrane components of the rat erythrocyte does not suggest any great difference in the rate of disappearance of the labelled membrane polypeptides. In other types of cell there seems to be a correlation between the size of a protein and its rate of degradation *in vivo*. The

MOLECULAR STRUCTURE OF NUCLEIC ACIDS

A Structure for Deoxyribose Nucleic Acid

WE wish to suggest a structure for the salt of deoxyribose nucleic acid (D.N.A.). This structure has novel features which are of considerable biological interest.

A structure for nucleic acid has already been proposed by Pauling and Corey¹. They kindly made their manuscript available to us in advance of publication. Their model consists of three intertwined chains, with the phosphates near the fibre axis, and the bases on the outside. In our opinion, this structure is unsatisfactory for two reasons: (1) We believe that the material which gives the X-ray diagrams is the salt, not the free acid. Without the acidic hydrogen atoms it is not clear what forces would hold the structure together, especially as the negatively charged phosphates near the axis will repel each other. (2) Some of the van der Waals distances appear to be too small.

Another three-chain structure has also been suggested by Fraser (in the press). In his model the phosphates are on the outside and the bases on the inside, linked together by hydrogen bonds. This structure as described is rather ill-defined, and for this reason we shall not comment on it.

We wish to put forward a radically different structure for the salt of deoxyribose nucleic acid. This structure has two helical chains each coiled round the same axis (see diagram). We have made the usual chemical assumptions, namely, that each chain consists of phosphate diester groups joining β -D-deoxy-ribofuranose residues with 3',5' linkages. The two chains (but not their bases) are related by a dyad perpendicular to the fibre axis. Both chains follow right-handed helices, but owing to the dyad the sequences of the atoms in the two chains run in opposite directions. Each chain loosely resembles Furbert's² model No. 1; that is, the bases are on the inside of the helix and the phosphates on the outside. The configuration of the sugar and the atoms near it is close to Furbert's 'standard configuration', the sugar being roughly perpendicular to the attached base. There is a residue on each chain every 3.4 Å. in the z-direction. We have assumed an angle of 36° between adjacent residues in the same chain, so that the structure repeats after 10 residues on each chain, that is, after 34 Å. The distance of a phosphorus atom from the fibre axis is 10 Å. As the phosphates are on the outside, cations have easy access to them.

The structure is an open one, and its water content is rather high. At lower water contents we would expect the bases to tilt so that the structure could become more compact.

The novel feature of the structure is the manner in which the two chains are held together by the purine and pyrimidine bases. The planes of the bases are perpendicular to the fibre axis. They are joined together in pairs, a single base from one chain being hydrogen-bonded to a single base from the other chain, so that the two lie side by side with identical z-co-ordinates. One of the pair must be a purine and the other a pyrimidine for bonding to occur. The hydrogen bonds are made as follows: purine position 1 to pyrimidine position 1; purine position 6 to pyrimidine position 6.

If it is assumed that the bases only occur in the structure in the most plausible tautomeric forms (that is, with the keto rather than the enol configurations) it is found that only specific pairs of bases can bond together. These pairs are: adenine (purine) with thymine (pyrimidine), and guanine (purine) with cytosine (pyrimidine).

In other words, if an adenine forms one member of a pair, on either chain, then on these assumptions the other member must be thymine; similarly for guanine and cytosine. The sequence of bases on a single chain does not appear to be restricted in any way. However, if only specific pairs of bases can be formed, it follows that if the sequence of bases on one chain is given, then the sequence on the other chain is automatically determined.

It has been found experimentally^{3,4} that the ratio of the amounts of adenine to thymine, and the ratio of guanine to cytosine, are always very close to unity for deoxyribose nucleic acid.

It is probably impossible to build this structure with a ribose sugar in place of the deoxyribose, as the extra oxygen atom would make too close a van der Waals contact.

The previously published X-ray data^{5,6} on deoxyribose nucleic acid are insufficient for a rigorous test of our structure. So far as we can tell, it is roughly compatible with the experimental data, but it must be regarded as unproved until it has been checked against more exact results. Some of these are given in the following communications. We were not aware of the details of the results presented there when we devised our structure, which rests mainly though not entirely on published experimental data and stereochemical arguments.

It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material.

Full details of the structure, including the conditions assumed in building it, together with a set of co-ordinates for the atoms, will be published elsewhere.

We are much indebted to Dr. Jerry Donohue for constant advice and criticism, especially on interatomic distances. We have also been stimulated by a knowledge of the general nature of the unpublished experimental results and ideas of Dr. M. H. F. Wilkins, Dr. R. E. Franklin and their co-workers at King's College, London. One of us (J. D. W.) has been aided by a fellowship from the National Foundation for Infantile Paralysis.

This figure is purely diagrammatic. The two ribbons symbolize the two phosphate-sugar chains, and the horizontal rods the pairs of bases holding the chains together. The vertical line marks the fibre axis. There is a residue on each chain every 3.4 Å. in the z-direction. We have assumed an angle of 36° between adjacent residues in the same chain, so that the structure repeats after 10 residues on each chain, that is, after 34 Å. The distance of a phosphorus atom from the fibre axis is 10 Å. As the phosphates are on the outside, cations have easy access to them.

The double helix: a personal view

Francis Crick

Medical Research Council Laboratory for Molecular Biology, Hills Road, Cambridge, UK

Francis Crick reviews the papers published 21 years ago on the structure of DNA and the reaction to them.

For this anniversary I thought it might be appropriate to look back, in a rather informal way, at the original papers on the structure of DNA to see how they appear today in the light of 21 years of research.

During the spring and summer of 1953 Jim Watson and I wrote four papers on the structure and function of DNA. The first appeared in *Nature* on April 25 accompanied by two papers from King's College London, the first by Wilkins, Stokes and Wilson, the other by Franklin and Gosling. Five weeks later we published a second paper in *Nature*, this time on the genetic implications of the structure. A general discussion was included in the volume that came from that year's Cold Spring Harbor Symposium, the subject of which was viruses. We also published a detailed technical account of the structure, with rough coordinates, in an obscure journal¹ in the middle of 1954.

The first *Nature* paper was both brief and restrained. Apart from the structure itself the only feature of the paper which has excited comment was the short sentence: "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material". This has been described as 'coy', a word that few would normally associate with either of the authors, at least in their scientific work. In fact it was a compromise, reflecting a difference of opinion. I was keen that the paper should discuss the genetic implications. Watson was against it. He suffered from periodic fears that the structure might be wrong and that he had made an ass of himself. I yielded to his point of view but insisted that something be put in the paper, otherwise someone else would certainly write to make the suggestion, assuming we had been too blind to see it. In short, it was a claim to priority.

Why, then, did we change our minds and, within only a few weeks, write the more speculative paper of May 30? The main reason was that when we sent the first draft of our initial paper to King's College we had not yet seen their own papers. Consequently we had little idea of how strongly their X-ray evidence supported our structure. The famous 'helical' X-ray picture of the B form, reproduced by Franklin and Gosling in their paper, had been shown to Watson, but he certainly had not remembered enough details to construct the arguments about Bessel functions and distances which the experimentalist gave. I myself, at that time, had not seen the picture at all. Consequently we were mildly surprised to discover that they had got so far and delighted to see how well their evidence supported our idea. Thus emboldened, Watson was easily persuaded that we should write a second paper.

The papers in *Nature*

The two experimental papers of April 25 overlap to a considerable extent. Rosalind Franklin's paper mentions the

crystalline A structure, but only briefly, except for the claim that the Patterson superposition function (which was in the press at the time) supported two chains rather than three. Both papers stress that there must be more than one chain in the structure. Indeed Maurice Wilkins had personally told Chargaff that a year or so earlier. Both present the argument that the positions of the intensity maxima ruled out two (parallel) chains related by a dyad parallel to the fibre axis. Neither gave the neat argument, due to Watson, that their own density measurement, together with the observed change in length between the two forms, supported two chains rather than three. Franklin noted that if there were several chains they could not be equally spaced and that 'equivalence' favoured two rather than three. It was not explicitly stated, however, that equivalence implies dyad axes perpendicular to the fibre axis and that therefore the two chains must run in opposite directions. Nor did she realise that the monoclinic unit cell of the A form also suggested this, although we had deduced this from her own experimental data.

Both papers correctly concluded from the intensity positions that the phosphate-sugar backbone was on the outside of the structure and that the bases were stacked on the inside. Franklin repeated the argument, which she had made to us verbally a year earlier, that the phosphates would be hydrated (in which she was perfectly right) and therefore that they would probably be on the outside of the molecule. In short, both the groups at King's College had obtained a fairly general idea of the structure but they had done no proper model building. Mainly because of this they had missed the pairing of the bases and they had completely overlooked the significance of Chargaff's rule.

The omissions in the paper by Watson and myself are also striking. The structure is produced like a rabbit out of a hat, with no indication as to how we arrived at it. No dimensions are given (let alone coordinates) except that the base pairs were 3.4 Å apart and that the structure had 10 base pairs in its repeat. The exact nature of the base pairing was not immediately obvious; nor even unambiguous since at that time there were two systems for numbering pyrimidine rings. Most of this information was provided in the subsequent papers. However the general nature of the structure was clear enough, though the tone of the paper ("it must be regarded as unproved until it has been checked against more exact results") was, apart from the short first paragraph, rather muted.

THE DOUBLE HELIX: A PERSONAL VIEW (F. Crick) . . .	766

Although a casual reader could easily have overlooked the significance of the first set of papers, especially as they were full of obscure crystallographic jargon, he could hardly miss the impact of our second one. The biologically important features of the proposed structure were explicitly described. The base pairs were listed with the minimum of hedging about tautomerism, and were illustrated in scale diagrams. The proposed duplication mechanism was spelt out in simple terms, unmarred by any trace of algebra. In spite of the discussion of the difficulties of unwinding, the list of unsolved problems and the reservations about the unproved nature of the structure, the final paragraph leaves little doubt that the authors thought they had a good idea.

How do they stand today?

How have these early papers stood the test of time? It can now be taken as firmly established that DNA usually consists of two chains, wound together and running in opposite directions. The evidence for this statement is so extensive that it would take too long to quote it all here. The fact that normally A pairs with T, and G with C, is also well established but the details were less certain until recently. The G:C pair was never in serious doubt. Watson and I drew this with only two hydrogen bonds but mentioned in our technical paper¹ that three was also a possibility. This was made almost certain by the theoretical arguments of Pauling and Corey² and was confirmed by X-ray structure determinations of single crystals of base pairs. The same technique showed that the A:T (or A:U) pair in single crystals usually did not have the configuration Watson and I suggested. The matter was only finally resolved about a year ago when Rich and his colleagues published two crystal structures; that of GpC paired with itself³ and ApU paired with itself⁴ (the backbone in each case was ribose), both to about 0.9 Å. They show not only the expected configurations for the base pairs but also make it highly likely that, as we claimed, nucleic acid helices are right handed.

In 1953 it was uncertain whether RNA could form a double helix. Watson and I stated that we thought we could not build our model for the B form of DNA with an RNA backbone. The discovery of double-stranded RNA viruses proved, however, that biological RNA too could form a double helix, though with slightly different parameters. The detailed coordinates we had (tentatively) suggested for DNA were soon shown to be incorrect (we had put the backbone at too big a radius) and much more accurate coordinates were provided by Wilkins and his colleagues, using fairly sophisticated methods of handling their much improved X-ray data. The general correctness of this work has been strongly supported recently by the single-crystal studies, mentioned above, of Rich and his coworkers.

Recently, Bram⁵ has put forward evidence that the parameters of a DNA double helix may vary somewhat with base composition, though whether this is a trivial variation or has deep biological implications is at present uncertain. Watson and I were so impressed with the apparent uniformity of the double helix from different biological sources and the regularity of the backbone of our model that we had no hesitation in saying that it "seems likely that the precise sequence of the bases is the code that carries the genetic information", an idea which gave me plenty to think about in the next 10 or 12 years.

Nothing was said about the possibility that the two chains might be melted apart and then annealed together again, correctly lined up. The discovery of this by Marmur and Doty has provided one of the essential tools of molecular biology. I can still remember the excitement I felt when Paul Doty told me about it at breakfast one day in New York in a hotel overlooking Central Park. But in other respects we were almost too far sighted, as witness our remark that recombination would probably depend upon

base pairing. We struggled for several years to produce neat models for this, all to no avail, partly because we accepted copy choice too easily but also because we were trying to invent a mechanism which did not need additional enzymes. This showed a gap in our overall grasp of molecular biology, which can also be glimpsed in our tentative suggestion that DNA synthesis might not need an enzyme, a remark I should certainly not make today except perhaps in the context of the origin of life.

As to DNA replication, our earliest description was mainly schematic. We realised that plain nucleotides were not likely to be the immediate precursor but missed the rather obvious idea that they were nucleoside triphosphates, again a lack of insight into biochemistry. We did suggest the so-called Y mechanism (in the Cold Spring Harbor paper) but did not mention the difficulties due to the direction of synthesis of antiparallel chains, though I frequently emphasised it a few years later. Looking back, I think we deserve some credit for not being inhibited by the difficulty of unwinding which we clearly recognised and for our forthright stand against paranemic (as opposed to plectonemic) coiling. In this instance our grasp of X-ray diffraction was invaluable.

The functions of DNA

It is, of course, somewhat a matter for surprise that DNA synthesis is not fully understood even today. It would take too much space to discuss the complex and rapidly moving field here. Semiconservative replication in many instances is firmly established. The process certainly occurs as if base pairing were taking place, but I have often asked myself what evidence would make it certain that base pairing really occurs rather than some elaborate allosteric mechanism, even though the latter seems unlikely. Perhaps only an X-ray determination of the structure of the polymerase will finally answer the question. Meanwhile the topics of Okazaki fragments, rolling circle models, RNA primers and the exact roles of the various polymerases will keep many people busy. Even at that early period we did at least ask whether the DNA of a chromosome was in one long molecule, though the idea of circular DNA never occurred to us. Nor did we suggest that a virus might have single-stranded DNA. There is however one remark which may turn out to be perspicacious "... we suspect that the most reasonable way to avoid tangling is to have the DNA fold up into a compact bundle as it is formed". As we struggle with the structure of the *E. coli* chromosome and the even more formidable problem of the structure of the chromosomes of higher organisms—probably the major unsolved problem of molecular biology today—it might be worth remembering this tentative suggestion from the distant past.

The other topic we touched on was mutation. This was of the base-substitution type—there is no hint of frameshift mutants. We totally missed the possible role of enzymes in repair although, due to Claud Rupert's early very elegant work on photoreactivation, I later came to realise that DNA is so precious that probably many distinct repair mechanisms would exist. Nowadays one could hardly discuss mutation without considering repair at the same time.

There is no hint in these early papers that nucleic acid might form a complex three-dimensional structure such as we now find in transfer RNA nor even the idea of the hypothetical Gierer loops. Our message was that DNA was simple and alone carried the genetic information. We saw no reason to complicate it till we had to. For the same reason although we must have drawn a G:U pair we attached no importance to it. "Wobble" was still far in the future, but these, it seems to me, are forgivable oversights.

Reactions to the structure

It is really for the historian of science to decide how our structure was received. This is not an easy question to

answer because there was naturally a spectrum of opinion which changed with time. There is no doubt, however, that it had a considerable and immediate impact on an influential group of active scientists. Mainly due to Max Delbrück, copies of the initial three papers were distributed to all those attending the 1953 Cold Spring Harbor Symposium and Watson's talk was added to the programme. A little later I gave a lecture at the Rockefeller which I am told produced considerable interest, partly I think because I mixed an enthusiastic presentation of our ideas with a fairly cool assessment of the experimental evidence, roughly on the lines of the article which appeared in *Scientific American* in October, 1954. Sydney Brenner, who had just finished his PhD, at Oxford under Hinshelwood, appointed himself, in the summer of 1954, as Our Representative at Cold Spring Harbor and took some pains to get the ideas over to Demerec. It was about this time that Matt Meselson, just moving into biology from physical chemistry, grasped the importance of inventing a new method to tackle the problem of semiconservative replication, a theoretical analysis which led to density gradient centrifugation. But not everyone was convinced. Barry Commoner insisted, with some force, that physicists oversimplified biology, in which he was not completely wrong. Chargaff, when I visited him in the winter of 1953-54, told me (with his customary insight) that while our first paper in *Nature* was interesting, our second paper on the genetic implications was no good at all. I was mildly surprised to find, when, some years later, in 1959, I talked with Fritz Lipmann who had arranged that I should give a series of lectures at the Rockefeller, that he had not really grasped our scheme of DNA replication. (It emerged that he had been talking to Chargaff.) By the end of the lectures, however, when he summed up, he gave a remarkably clear outline of our ideas. Arthur Kornberg has told me that when he began work on DNA replication he did not believe in our mechanism, but his own brilliant experiments soon made him a convert, though always a careful and critical one. It was his work which produced the first good evidence that the two chains run in opposite directions. All in all it seems to me that we got a very fair hearing, better than Avery and certainly a lot better than Mendel.

Not that it was all plain sailing. We were naturally delighted with the work of Meselson and Stahl, and of Herbert Taylor, on semiconservative replication, though I have never thought this the essence of our ideas which lies rather in the base pairing. Seymour Benzer's genetic analysis of the r_{II} locus of phage T4 encouraged us greatly. But we had to live through the claims of Marshak that there was no DNA in *Arbacia* eggs and of a Canadian group that the amount of DNA synthesis in one cell cycle was twice the expected amount. At a later stage Cavalieri claimed that the basic DNA structure had four chains, rather than two, an idea which cropped up again more recently. On the crystallographic side Donohue, whose advice had been crucial to our understanding of base pairing, was a persistent critic of the validity of the later X-ray work, but in recent years he carried it too far, refusing, for example, to admit as evidence the great accumulation of data showing that the two chains are antiparallel. (In 1956, he had rashly published, with Stent, a quite erroneous structure having like-with-like pairing.) I hope the recent papers by Rich, referred to above, have to some extent reduced his doubts, which at times had some justification.

Who might have discovered it?

Then there is the question, what would have happened if Watson and I had not put forward the DNA structure? This is 'iffy' history which I am told is not in good repute with historians, though if a historian cannot give plausible answers to such questions I do not see what historical analysis is

about. If Watson had been killed by a tennis ball I am reasonably sure I would not have solved the structure alone, but who would? Olby⁶ has recently addressed himself to this question. Watson and I always thought that Linus Pauling would be bound to have another shot at the structure once he had seen the King's College X-ray data, but he has recently stated that even though he immediately liked our structure it took him a little time to decide finally that his own was wrong. Without our model he might never have done so. Rosalind Franklin was only two steps away from the solution. She needed to realise that the two chains must run in opposite directions and that the bases, in their correct tautomeric forms, were paired together. She was, however, on the point of leaving King's College and DNA, to work instead on TMV with Bernal. Maurice Wilkins had announced to us, just before he knew of our structure, that he was going to work full time on the problem. Our persistent propaganda for model building had also had its effect (we had previously lent them our jigs to build models but they had not used them) and he was proposing to give it a try. I doubt myself whether the discovery of the structure could have been delayed for more than two or three years.

There is a more general argument, however, recently proposed by Gunther Stent and supported by such a sophisticated thinker as Medawar. This is that if Watson and I had not discovered the structure, instead of being revealed with a flourish it would have trickled out and that its impact would have been far less. For this sort of reason Stent had argued that a scientific discovery is more akin to a work of art than is generally admitted. Style, he argues, is as important as content.

I am not completely convinced by this argument, at least in this case. Rather than believe that Watson and Crick made the DNA structure, I would rather stress that the structure made Watson and Crick. After all, I was almost totally unknown at the time and Watson was regarded, in most circles, as too bright to be really sound. But what I think is overlooked in such arguments is the intrinsic beauty of the DNA double helix. It is the molecule which has style, quite as much as the scientists. The genetic code was not revealed all in one go but it did not lack for impact once it had been pieced together. I doubt if it made all that difference that it was Columbus who discovered America. What mattered much more was that people and money were available to exploit the discovery when it was made. It is this aspect of the history of the DNA structure which I think demands attention, rather than the personal elements in the act of discovery, however interesting they may be as an object lesson (good or bad) to other workers.

My own reactions

I have sometimes been asked whether I had ever contemplated writing my own account of the discovery. In the 1950s I did give a lecture on this subject to a group of historians of science at Cambridge and to a similar group at Oxford. I was able to be rather more scholarly than Watson could allow himself in *The Double Helix*, which is better regarded as a rather vivid fragment of his autobiography, written for a lay audience. As to a book I confess I did get as far as composing a title (*The Loose Screw*) and what I hoped was a catchy opening ("Jim was always clumsy with his hands. One had only to see him peel an orange. . .") but I found I had no stomach to go on. Recently we made a film together about it for undergraduates. Much had to be left out when the film came to be cut but it does to some extent supplement Jim's book. Since Olby's detailed and scholarly account⁶ will soon be available I doubt if there is now much more I can usefully add.

Finally one should perhaps ask the personal question—am I glad that it happened as it did? I can only answer that

I enjoyed every moment of it, the downs as well as the ups. It certainly helped me in my subsequent propaganda for the genetic code. But to convey my own feelings, I cannot do better than quote from a brilliant and perceptive lecture I heard years ago in Cambridge by the painter John Minton (he later committed suicide) in which he said of his own artistic creations "the important thing is to be there when the picture is painted". And this, it seems to me, is partly a matter of luck and partly good judgement, inspiration and persistent application.

Molecular basis of biological specificity

Linus Pauling

Institute of Orthomolecular Medicine, 2700 Sand Hill Road, Menlo Park, California 94025

Linus Pauling reviews his work on the molecular basis of biological specificity and remembers his erroneous conception of a three-chain helix structure for DNA in 1952.

DURING the decade 1930-40 I formulated a general theory of the molecular basis of biological specificity, involving the idea that biological specificity results from the interaction of complementary molecular structures, with hydrogen bonds among the most important of the weak intermolecular forces between the interacting molecules. The most striking example of specific biological interactions of this sort is the interaction between the two complementary strands of the DNA molecule in the double helix discovered by Watson and Crick 21 years ago.

Early work

My early work was on the determination of the structure of crystals by the X-ray diffraction technique, the determination of the structure of gas molecules by electron diffraction, and the application of quantum mechanics to physical and chemical problems, especially the structure of molecules and the nature of the chemical bond. In 1929, when Thomas Hunt Morgan came to the California Institute of Technology, bringing with him a number of very able younger biologists, I began to become familiar with biological problems, and to think about possible ways in which biological specificity could be explained in terms of interactions between molecules. I worked on several problems of biological specificity, from the molecular point of view, without success; one of them was the problem of explaining the self sterility of the marine organism *Ciona* (the sea squirt), which was being studied by Morgan. In 1934 the problem of the shape of the oxygen equilibrium curve of haemoglobin attracted my attention. Consideration of the structure of haemoglobin led to the idea that investigation of the magnetic properties of this substance and its derivatives would provide valuable information, and work along these lines, in collaboration with C. D. Coryell and a number of students, was initiated. Alfred E. Mirsky of the Rockefeller Institute for Medical Research, who had been studying haemoglobin for several years, came to Pasadena for a year, and he and I formulated a theory of the structure of native, denatured, and coagulated proteins, based upon the concept that a native protein molecule consists of one polypeptide chain (or of two or more such chains) folded into a uniquely defined configuration, in which

it is held by hydrogen bonds between the peptide nitrogen and oxygen atoms, as well as by other weak forces, with denaturation involving a loss of this well-defined structure¹.

Antigens and antibodies

In 1936, while I was on a short visit to the Rockefeller Institute for Medical Research, Karl Landsteiner asked me how I would explain the observed properties of antibodies and antigens by means of their molecular structure. I thought about this problem during the following years, and consulted Landsteiner about the interpretation of sometimes conflicting experimental results. By 1940 I had formulated a theory of the structure, and process of formation of antibodies². This theory was based upon the concept that the specific combining region of an antibody molecule is complementary in structure to a portion of the surface of the antigen, with the antigen-antibody bond resulting from the cooperation of weak forces (electronic Van der Waals forces, electrostatic interaction of charged groups, and hydrogen bonding) between the complementary structures, over an area sufficiently large that the total binding energy could resist the disrupting influence of thermal agitation. Precipitating and agglutinating antibodies were assumed to be bivalent, consisting of a central part, with structure common to all or almost all antibodies produced by the animal, and two end parts, the combining regions, with structure complementary to that of the antigen. (The idea of complementary structures for antibody and antigen was suggested by Breml and Haurowitz³, Alexander⁴, and Mudd⁵. There is some intimation of it in the early work of Ehrlich and Bordet.) The complementary combining regions were assumed to be formed by the folding of polypeptide chains in the presence of the antigen, in such a way that the forces of attraction would mould the folding chain into a structure complementary to that of a portion of the antigen, with the folded chain then being held in this configuration by hydrogen bonds and other interactions, even after the antibody has dissociated from the antigen on which the combining group was moulded. Dan Campbell, David Pressman, and a number of other workers in our laboratory carried out experimental studies that verified the valence 2 for precipitating and agglutinating antibodies^{6,7} and that left no doubt that the combining regions of antibodies are complementary in structure to the homologous haptens or groups of the antigen⁸. The fit of the combining region of the antigen to the hapten was shown to be close, better than 20 pm in some cases, and the effects of Van der Waals attraction, electrostatic forces, and hydrogen-bond formation were

separately verified in quantitative hapten-inhibition studies. A satisfactory theoretical explanation of quantitative values of free energy of combination of haptens with antibodies homologous to the *o*-, *m*-, and *p*-azobenzene arsenic acid groups on the basis of known intermolecular interactions was reported in 1945 (ref. 9). For several haptens with various groups substituted in the positions of the azo group in the hapten of the immunising antigen the standard free energy of combination, as given by hapten inhibition constants, was found to be proportional to the calculated Van der Waals interaction with the surrounding antibody, which includes proportionality to the electric polarisability of the group. For groups forming hydrogen bonds the energy of the hydrogen bond (1.5 to 3 kJ mol⁻¹, representing the difference in energy of the hydrogen bond formed by the hapten with antibody and with water) was needed, in addition to the term corresponding to electronic Van der Waals interaction. The effect of electric charge was determined by comparison of haptens closely similar in shape, but with a difference in electric charge: in one case¹⁰ comparison of haptens with either trimethylammonium ion or tertiary butyl group, and in the other case¹¹ with either carboxylate ion or nitro group. In each comparison there was indication of a complementary electric charge in the antibody, close to the charge in the immunising antigen. The magnitude of the effect showed the charge in the antibody to be within 320 pm (first case) or 260 pm (second case) of the minimum distance permitted by the Van der Waals radii of the groups. I think that this work, which was based on earlier work by Landsteiner and his collaborators¹², leaves no doubt that the specificity of antibodies is the result of the complementarity in structure of the combining group and a portion of the surface of the homologous antigen.

Nonbiological specificity

It became evident that nonbiological specificity could also be explained in terms of complementarity. I gave an example in a lecture on analogies between antibodies and simpler chemical substances¹³. "The reaction shown by simple chemical substances that is analogous to that of specific combination of antigen and antibody is the formation of a crystal of a substance from solution. A crystal of a molecular substance is stable because all of the molecules pile themselves into such a configuration that each molecule is surrounded as closely as possible by other molecules—that is, if a molecule were to be removed from the interior of a crystal, the cavity that it would leave would have very nearly the shape of the molecule itself. We can say that the part of a crystal other than a given molecule is very closely complementary to that molecule. Other molecules, with different shape and structure, would not fit into this cavity nearly so well, and in consequence other molecules in general would not be incorporated in a growing crystal. This is the explanation of the astounding chemical process of purification by crystallization—from a very complicated system, such as, for example, grape jelly, containing hundreds of different kinds of molecules, crystals which are nearly chemically pure may be formed, such as crystals of cream of tartar, potassium hydrogen tartrate".

In the same paper it is stated that "although crystallisation is the only simple chemical reaction that shows striking similarity to serological reactions with respect to specificity, there are many physiological phenomena that are similarly specific, and for which the specificity can be given a similar explanation. The specificity of the catalytic activity of enzymes is due to a surface configuration of the enzyme such as to make the enzyme complementary to the substrate molecule or, rather, to the substrate molecule in the strained state that occurs during the catalysed reaction. The specific action of drugs and bactericidal substances have a similar explanation. Even the senses of taste and odour are based

upon molecular configuration rather than upon ordinary chemical properties—a molecule which has the same shape as a camphor molecule will smell like camphor even though it may be quite unrelated to camphor chemically. I am convinced that it will be found in the future, as our understanding of physiological phenomena becomes deeper, that the shapes and sizes of molecules are of just as great significance in determining their physiological behavior as are their internal structure and ordinary chemical properties."

Intermolecular forces in biological processes

In 1940 Max Delbrück and I¹⁴ published a discussion of the intermolecular forces operative in biological processes. P. Jordan had advanced the idea that there exists a quantum-mechanical stabilising interaction that operates preferentially between identical or nearly identical molecules or parts of molecules, and is of great importance for biological processes, including the production of new genes identical with the old ones. Delbrück and I pointed out that the specific quantum-mechanical forces between identical molecules could not be large enough to cause a specific attraction between like molecules under the conditions of excitation and perturbation prevailing in living organisms, and therefore could not be effective in bringing about autocatalytic reactions. We wrote that "It is our opinion that the processes of synthesis and folding of highly complex molecules in the living cell involve, in addition to covalent-bond formation, only the intermolecular interactions of Van der Waals attraction and repulsion, electrostatic interactions, hydrogen-bond formation, etc., which are now rather well understood. These interactions are such as to give stability to a system of two molecules with complementary structures in juxtaposition, rather than of two molecules with necessarily identical structures; we accordingly feel that complementarity should be given primary consideration in the discussion of specific attraction between molecules and the enzymatic synthesis of molecules." We mentioned that "The case might occur in which the two complementary structures happened to be identical; however, in this case also the stability of the complex of two molecules would be due to their complementarity rather than their identity." Some time later¹⁵ I discussed the matter of gene replication in more detail: "I believe that the genes serve as the templates on which are molded the enzymes that are responsible for the chemical characters of the organisms, and that they also serve as templates for the production of replicas of themselves. The detailed mechanism by means of which a gene or a virus molecule produces replicas of itself is not yet known. In general the use of a gene or virus as a template would lead to the formation of a molecule not with identical structure but with complementary structure. If might happen, of course, that a molecule could be at the same time identical with and complementary* to the template on which it is molded. However, this case seems to me to be too unlikely to be valid in general, except in the following way. If the structure that serves as a template (the gene or virus molecule) consists of, say, two parts, which are themselves complementary in structure, then each of these parts can serve as the mold for the production of a replica of the other part, and the complex of two complementary parts thus can serve as the mold for the production of duplicates of itself." The same statements were made in the spring of 1948 in lectures in Oxford, Cambridge, London and elsewhere.

The hydrogen bond was recognised by Latimer and Rodebush as an important structural feature more than 50 years ago¹⁶. In their 1920 paper they mentioned that "Mr Huggins of this laboratory in some work as yet unpublished has used the idea of a hydrogen kernel held between two atoms as a theory in regard to certain organic compounds." In 1936 Mirsky and I pointed out the importance of the hydrogen bond in determining the structure of proteins¹. In the same

year Huggins also discussed protein structures in a more detailed way, with hydrogen bonds between the NH and CO groups of the main chains¹⁷. A few years later Huggins described several helical structures for polypeptide chains, with intrachain hydrogen bonds¹⁸. These structures were needlessly restricted to having an integral number of amino acid residues per turn of the chain and, moreover, Huggins did not require the amide groups to be planar, although the planarity of these groups had been recognised since 1932 (ref. 19), and had already been verified by several determinations of the structure of simple peptide crystals in our laboratory. It is unfortunate that Huggins was handicapped by these two erroneous assumptions in his imaginative and otherwise sound attack on the problem of the secondary structure of proteins. The same two erroneous assumptions provided a similar insuperable barrier to the vigorous attack made by Bragg, Kendrew, and Perutz on the same problem²⁰. In the meantime, Corey and other investigators in Pasadena had determined the crystal structures of a number of amino acids and simple peptides, and Corey and I had discovered the alpha helix and the parallel chain and antiparallel chain pleated sheets²¹. The discovery of the alpha helix left no doubt about the importance of helical structures and of hydrogen bonds in determining the secondary structures of proteins.

Nucleic acids

I had been interested in the nucleic acids since 1933, when Sherman and I calculated the resonance energy of guanine and other purines²². My colleague Robert B. Corey had made some X-ray diffraction photographs of fibres of nucleic acid, which were, however, of somewhat poorer quality than those published by Astbury and Bell²³. I began work on the problem of interpreting the X-ray photographs on November 26, 1952; on the preceding day I had attended a seminar in biology in the California Institute of Technology, at which Professor Robley Williams of University of California, Berkeley, showed a slide of an electron microscope photograph of molecules of sodium ribonucleate. He said that the small fibrils had a diameter of about 1.5 nm, and that they were apparently cylindrical, in that only one diameter was shown. The X-ray photographs indicated an identity distance along the axis of the molecule of 340 pm, and, with the measured density of RNA, about 1.62 g cm⁻³, it was indicated that the fibres contain two or three molecules, probably helices twisted about one another. The value of the spacing of the principal equatorial X-ray reflection had been shown to decrease with decreasing amount of hydration of the fibres, with a minimum value of 1.62 nm. I assumed this value to correspond to essentially anhydrous nucleic acid, and, using the density, I calculated the number of polynucleotide chains per unit to be exactly three. This result surprised me, because I had expected the value 2 if the nucleic acid fibres really represented genes. I decided, however, that probably the fibres were artefacts, produced by the process of extraction from cells and the subsequent stretching. During the next month I strove to find a way of arranging the polynucleotide chains in a triple helix, and was successful, although the structure was described as "an extraordinarily tight one, with little opportunity for change in positions of the atoms". The paper in which this structure was described was communicated to the *Proceedings of the National Academy of Sciences* on December 31, 1952, and a copy of the manuscript was sent to Watson and Crick²⁴.

In hindsight, it is evident that I made a mistake on November 26, 1952 in having decided to study the triple helix rather than the double helix. It is likely that the fibres giving the equatorial spacing 1.62 nm contained some water, and also had a density less than 1.62 g cm⁻³. The diameter 1.5 nm observed by Williams for nucleic acid molecules corresponds, with an assumed density of 1.6 g cm⁻³ and unit translation 340 pm along the molecular axis, to two molecules in a

helical structure (calculated diameter 1.6 nm) rather than to three (1.9 nm). I am now astonished that I began work on the triple helix structure, rather than on the double helix. I had not forgotten that Delbrück and I had suggested that the gene might consist of two complementary molecules, but for some reason, not clear to me now, the triple chain structure apparently appealed to me, possibly because the assumption of a three-fold axis simplified the search for an acceptable structure.

I cannot say what would have happened if I had made the other assumption, that of a double helix, on November 26, or if I had succeeded in getting access to the diffraction photographs of DNA that had been made by Wilkins. There is a chance that I would have thought of the Watson-Crick structure during the next few weeks. I knew that the purines and pyrimidines were present in nucleic acid in equal amounts, but I had not drawn the reasonable conclusion about purine-pyrimidine pairs. I knew about hydrogen bonding by purines and pyrimidines. Nevertheless, I myself think that the chance is rather small that I would have thought of the double helix in 1952, before Watson and Crick made their great discovery. After all, I had spent part of the summer of 1937 in a search for ways of folding polypeptide chains, with planar amide groups of the correct dimensions and with hydrogen bonds between the CO and NH groups of residues separated by some distance along the chain, in such a way as to account for the X-ray diffraction photographs of alpha keratin, but without success. There was no reason why the alpha helix should not have been discovered then, rather than 11 years later, when it was discovered after a few hours of work. There is no doubt that even rather simple ideas sometimes are very elusive.

It is my opinion that if Watson and Crick had not carried on their persistent effort, and had not had the benefit of advice about the structures of the nitrogen bases and hydrogen bonds from Jerry Donohue and information from the excellent X-ray diffraction photographs of Wilkins, the discovery of the double helix, which has led to such great developments in molecular biology, might well have been delayed for several years.

Molecular biology in a living cell

J. B. Gurdon

Medical Research Council Laboratory of Molecular Biology, Hills Road, Cambridge, UK

Dr Gurdon discusses the introduction of purified macromolecules, such as nucleic acids and proteins, into living cells in controlled amounts and in such a way that they function normally.

MUCH of the success of molecular biology during the past 20 years has stemmed from the development of methods for purifying macromolecules. Initially this opened the way towards a detailed description of the composition and three-dimensional structure of macromolecules. Subsequently, it enabled the function of identified cell components such as nucleic acid polymerases, messenger RNA and initiation factors, to be determined using cell-free systems which synthesise DNA, RNA or protein. There are however certain questions about the function and behaviour of macromolecules which are unlikely to be answered by a knowledge of their structure and of their behaviour in cell-free systems. These are questions, moreover, which could be answered if it were possible to introduce purified macromolecules into living cells in significant amounts and in such a way that they function normally. This article summarises what is known of the fate of purified macromolecules inserted into living cells, and outlines some of the present and future uses for this particular type of molecular biology.

Macromolecules do not enter cells at all readily under normal conditions¹ (see Fig. 1a). There are exceptions to this rule, such as the passage of some hormones into responsive cells, the uptake of RNA by macrophages and the events involved in virus infection, but in these cases cells possess special receptors or mechanisms for the selective uptake of a restricted range of molecules. Even when agents are used which increase incorporation, such as DEAE dextran^{2,3}, purified molecules, such as RNAs, are susceptible to breakdown if added to undefined media of the kind preferred by growing cells. Only a small proportion of macromolecules in the medium enter a cell over many hours and those which do may be partly degraded. A different approach to the problem is to inject a solution of macromolecules directly into a living cell. By this means, a known number of purified macromolecules can be inserted directly into a living cell without significant contact with the external medium. The manipulations required⁴ are relatively undemanding so long as large cells are used as recipients. Here special emphasis is given to injection experiments with amphibian eggs and oocytes; these cells are especially suitable for such experiments on account of their large size, which permits quantitative work, and their developmental potentiality, which, in the case of eggs, ensures that injected molecules are distributed to different kinds of specialised cells.

Experiments involving the injection of macromolecules into living cells fall into two categories. The first includes attempts to validate injection experiments by proving that introduced macromolecules are accepted in a normal and functional way by the recipient cells. The second involves the application of this technique to specific questions about the characteristics of the injected molecules and the recipient cells.

Validity of injection experiments

We need to know that injected molecules are not rapidly

broken down or eliminated from cells, that they are not toxic in moderate amounts, that they are distributed in cells in their characteristic way, and that they function normally. The most exacting test of these requirements is provided by following the fate of injected macromolecules which have been purified away from other molecules with which they are always associated in cells. As far as is known such molecules as messenger RNA and DNA never exist in cells free and uncomplexed with proteins. Another kind of sensitive test

Fig. 1. Autoradiographs of sections of blastulae grown from eggs in which one of the blastomeres was injected at the four-cell stage with *Xenopus* erythrocyte histones labelled with ¹²⁵I. a, Two cleavage cells, which are presumed to be daughters of the same parent cell, and which have intensely labelled nuclei. The neighbouring cells, presumed to have been derived from uninjected blastomeres, are completely unlabelled. Evidently labelled histones do not pass freely across cell walls. b, Autoradiographic grains over chromosomes on a metaphase spindle. Some of the injected ¹²⁵I-histones appear to have become associated with chromosomes. These are the results of unpublished experiments with W. M. Bonner.

TABLE 1 Tolerance of fertilised *Xenopus* eggs to injected macromolecules

Injected molecules			Survival§, ¶		Relative increase§,		
Type	No. per egg	Weight per egg†	% injected Blastula (st. 9)	eggs surviving to Tadpole (st. 40)	Injected molecules as a proportion of embryos' normal content of equivalent molecules		
					Fertilised egg (st. 1)	Blastula (st. 9)	Tadpole (st. 40)
Proteins*							
Total histones (<i>Xenopus</i>)	5×10^{12} 5×10^{11}	100 ng 10 ng	Mostly abnormal 85%	4% 52%	0.2	0.05	0.005
					(relative to total histone)		
Histone f2a2 (calf thymus)	5×10^{11}	10 ng	94%	67%	1.0	0.25	0.025
					(relative to histone f2a2)		
Myoglobin (whale)	5×10^{11}	20 ng	83%	72%	Myoglobin probably absent from eggs and blastulae		Probably low in tadpoles
RNA†							
Globin mRNA (rabbit or mouse)	5×10^{10}	18 ng	82%	41%	1.0	1.0	0.2
					(relative to total poly (A)-mRNA)		
DNA							
Total chromosomal	2×10^8	4 ng	Mostly abnormal	2%	100	0.005	0.0004
(native calf thymus)	5×10^7	1 ng		84%			
(10 ⁷ daltons)							
Polyoma virus (form I native closed circles)	5×10^6	0.02 ng	88%	40%			
Injection medium							
Control	—	—	90%	86%	—	—	—

This table shows the upper limits of tolerance of fertilised eggs, which are more sensitive than oocytes, to introduced macromolecules. Survival to the tadpole stage is a sensitive test of toxicity (see below). Some frog species have larger eggs with greater tolerances.

* Unpublished experiments of W. M. Bonner and J. B. G.

† Refs 8 and 22.

‡ Each sample was injected in a volume of 20 nl per egg.

§ For stage numbers see ref. 43.

¶ Up to 5% survival to tadpoles may be attributed to eggs in which excessive leakage has occurred, and which are not therefore a proper test of toxicity. Survivals of 75% or more are not distinguishable from total nontoxicity, because some eggs are congenitally abnormal. || Values for the normal content of proteins and mRNA are approximate. The histone content of cleavage embryos is certainly in considerable excess of their nuclear DNA content but may be smaller than the values used to make these calculations (see ref. 27). Eggs contain ~30 ng of poly(A)-containing RNA⁴⁴, but only ~2% of this is being translated on polysomes (H. R. Woodland, unpublished). Relative to fertilised eggs blastulae contain twice as much, and tadpoles about 20 times as much, polysome-associated mRNA (H. R. Woodland, unpublished). Leakage and breakdown (see text) have not been allowed for in comparing the amounts of injected and endogenous molecules.

is provided by following the fate of injected molecules which normally have a characteristic intracellular distribution; examples of these are histones which are synthesised in cell cytoplasm but which very rapidly enter and accumulate in the nucleus⁵.

The leakage or rapid breakdown of injected molecules has been tested by following the fate of ³H-labelled DNA or ¹²⁵I-labelled histones. The disappearance of acid-insoluble label often amounts to 20–30% within the first few hours after injection, but after this its rate of loss is less than 10% per day. Experiments with globin mRNA (below) suggest that it has a half life of more than one week. The electrophoretic analysis of material extracted from tadpoles 3 days after they were injected, at the egg stage, with ¹²⁵I-histone fractions F2a1 and F2b showed the presence of these two proteins as the major labelled components (W. M. Bonner, unpublished experiments involving the injection of separated fractions of calf thymus histones and unfractionated *Xenopus* erythrocyte histones into oocytes and eggs). Apparently most of the injected proteins and nucleic acids are not rapidly eliminated or broken down.

Toxicity tests have been carried out to determine the numbers of different molecules that can be tolerated by oocytes and eggs. If fertilised eggs, which are much more sensitive than oocytes, can develop into normal tadpoles, the injected molecules are considered nontoxic. Table 1 shows the maximum amounts tolerated by a *Xenopus* egg, that is about 1 ng of DNA, and 10–20 ng (~10¹¹ molecules) of proteins or RNA. These numbers of molecules are entirely sufficient for most experimental analyses to be carried out on a small number of eggs (about 10).

The tendency of injected molecules to take up their normal intracellular distribution has been examined by following autoradiographically the fate of ¹²⁵I-histones injected into oocytes and eggs. Labelled histones show a spectacular accumulation in the nucleus of an oocyte; after 12 h they are

about 100 times more concentrated in the nucleus than in the cytoplasm⁶, a situation which can result in the nucleus containing several hundred times more than its normal content of histone associated with DNA. Histones also accumulate strongly in the nuclei of fertilised cleaving eggs (Fig. 1a). The same nuclear accumulation is not shown by nonnuclear proteins such as bovine serum albumin, nor by proteins of the same size range (myoglobin) or charge (lysozyme) as histones (W. M. Bonner, unpublished). The examination of metaphase chromosomes suggests that at least some of the injected histones become associated with chromosomes (Fig. 1b). Separated calf thymus histone fractions give broadly similar results to those just outlined for *Xenopus* erythrocyte histones. Some of the injected mRNA seems also to take up its normal location in injected cells, since globin mRNA becomes incorporated into polysomes (mostly pentasomes)⁷ and its translation is inhibited by cycloheximide⁸. The fate of DNA injected into fertilised eggs is now under investigation, but other work on DNA which enters cultured plant or animal cells has shown that some of the DNA is included in the nucleus^{9,10}, and may be linked to chromosomal DNA^{11,12}.

Evidence for the normal function of injected macromolecules has come from experiments with RNA and DNA, since the function of histones is not known. Results obtained with globin mRNA have shown conclusively that some of the injected molecules can function normally. α and β globin mRNAs of the rabbit, mouse and duck are all translated accurately, as judged by several different types of analysis of oocyte-synthesised haemoglobin, globin and globin peptides^{13–15}. Furthermore, the injected mRNA is used efficiently; appropriate calculations¹⁶ suggest that, on average, one globin molecule is synthesised in oocytes from each mRNA every 2 min. This is about four times less often than would have been the case in rabbit reticulocytes at 19° C. If, however, some of the injected molecules leak out, are broken down, or

Fig. 2 Stability of globin messenger RNA in *Xenopus* oocytes. Purified mouse globin mRNA (7 ng per oocyte) was injected into several groups of oocytes which were incubated in unlabelled medium. At intervals, a group was transferred to ^3H -histidine-containing medium for 12 h, and then analysed for the ratio of labelled haemoglobin to labelled endogenous proteins (●) and for the ratio of α globin to β globin synthesis (○). Details in ref. 16.

are defective, the efficiency with which some of the injected molecules are translated would be close to what is normal for the cells from which they were prepared.

Evidence for the function of injected DNA has been obtained for replication, though not as yet for transcription. The strongest case for replication of DNA has come from the injection of double-stranded supercoiled polyoma virus DNA into eggs¹⁷. The tests carried out include the demonstration that heavy:light parental molecules, density-labelled with BUDR on one strand, cause the appearance in eggs of light:light double-stranded molecules. ^3H -TdR incorporation was observed into new strands which were complementary, and hydrogen bonded, to the density-labelled parental strands. Since the newly synthesised polyoma DNA was selectively extracted, and purified in alkaline sucrose gradients as 53S molecules, it is evidently present as closed supercoiled circles. The egg cytoplasm has apparently been able to open the parental supercoils, synthesise a copy semiconservatively, separate the newly synthesised molecules, and close them up into circles. It seems that different kinds of vertebrate native DNA will serve as a template for replication in egg cytoplasm¹⁸, but do so to a much lesser extent in oocyte cytoplasm^{19,20}. This difference is important since the behaviour of injected molecules reflects the normal metabolic difference between oocytes and eggs in respect of DNA synthesis, a result which gives confidence in the significance of such experiments.

These results with RNA and DNA allow us to conclude that macromolecules can be purified away from their natural association with other molecules, injected free into the cytoplasm of eggs and oocytes, and still carry out some of their normal functions. These results, together with the evidence presented that injected molecules are not rapidly degraded or toxic, justify attempts to use injection experiments for investigating certain properties of injected molecules and recipient cells.

Specific applications of injection experiments

The following experiments have given results which would not have been predicted; they have been selected to show how the introduction of macromolecules into living cells can provide information not readily obtained by other means. The examples selected concern secondary modification of proteins, message stability, message-specific translational factors, and *in vivo* DNA polymerase assays.

Many kinds of proteins are secondarily modified after synthesis; molecular injection experiments have led to the conclusion that the enzymes involved are surprisingly general. Table 2 shows that frog egg or oocyte cytoplasm can modify correctly a range of proteins which they would never normally encounter. This lack of cell-type specificity of modifying enzyme systems suggests that the existence of modified pro-

teins in a cell is determined by the availability of amino acid sequences on which enzymes act and not by the availability of the enzymes themselves.

The stability of mRNA can vary substantially from one kind of message and cell type to another²¹, and message instability could be important for ensuring a changing population of new proteins as cells differentiate. The introduction of mRNA into a cell which is not synthesising that kind of mRNA provides a very sensitive test of mRNA stability under *in vivo* conditions. As seen in Fig. 2, α and β -globin mRNAs continue to be translated in oocytes for as long as 2 weeks, and without any obvious reduction in efficiency. Comparable experiments have been carried out in fertilised eggs²² and again the injected messages continued to be translated for as long as a week; by this time, over 15 cycles of cell division had been passed through, and the eggs had developed into swimming tadpoles, which were still synthesising rabbit haemoglobin. This remarkable stability of globin mRNA excludes the possibility that there is a general mechanism in oocytes or embryos which degrades all kinds of messages. Any natural message which is short lived in these embryos must evidently have RNase sensitivity coded into it, or must be specially complexed or compartmentalised in the cell.

Specialised cells are believed to contain molecules which enhance the translation of their characteristic messages²³. The effect of these message-specific factors is seen in cell-free systems. The unnatural composition of *in vitro* systems however, could result in a dependence on such factors in a way that would not be true of living cells. The use of injection experiments for investigating the role of message-specific factors and the control of translation in general demands careful quantitative control over the injection of nanolitre volumes of material. That this can be achieved in living cells is seen from the message saturation curves in Fig. 3. The injection of more than 10 ng of globin mRNA saturates the cell, and some component other than mRNA then limits the rate of its translation. Furthermore a message, once established, is displaced only slightly if at all by large amounts of other injected messages⁴⁹. This information makes it possible to carry out tests for the existence of message-specific factors by injecting mRNA into an oocyte which has previously been saturated with a different kind of mRNA. If the translation of a second message is unaffected by whether the cell has been previously saturated with the first message, this implies the existence of message-specific factors. Such experiments have been carried out in which globin and encephalomyocarditis (EMC)

Fig. 3 Message saturation curves obtained by injecting increasing concentrations of mRNA or polysomes (for rabbit globin) into *Xenopus* oocytes. In calculating mRNA concentrations, it has been assumed that globin mRNA is 100% of the repurified 9S RNA of reticulocytes, and is 1.5% of the total RNA of polysomes. These experiments were carried out and analysed according to the procedures described in ref. 49. At least part of the difference in the saturation levels of polysomes (○) and pure mRNA (●) is due to the more efficient translation of α -globin mRNA in polysomes (which were in this case a crude preparation containing haemin)¹⁶. These are unpublished results obtained in collaboration with G. Marbaix.

TABLE 2 Secondary modifications of proteins in *Xenopus* oocytes

Protein	Modification in normal tissue of origin	Cell type in which protein is normally synthesised and modified	Evidence for modification in frog oocytes
α A2 crystallin	Acetylation of N-terminal methionine	Calf lens epithelium	N-acetyl methionine in N-terminal peptide ⁴⁵
Stable proteins of EMC virus	Cleavage of primary polypeptide	Mouse ascites cells	³⁵ S-methionine labelled virion proteins ¹⁷
Protamine	Phosphorylation	Trout testis	Phosphorylated peptides (unpublished work with G. Dixon)
Immunoglobulin light chain	Removal of ~15 amino acids from primary polypeptide	Mouse myeloma cells	Size of labelled light chains ^{46,47}
Collagen	Hydroxylation of proline	Cultured mammalian fibroblasts	Hydroxyproline in labelled protein ⁴⁸

Oocytes were injected with mRNA coding for the proteins specified, and then allowed to incorporate labelled amino acids. Labelled proteins were extracted and analysed. There are indirect, though strong, arguments against the possibility that the message samples contained contaminating messages for the modifying enzymes, as explained in references cited. This list includes all tests for secondary modifications so far completed.

virus RNA compete against each other. The translation of one of these messages is very largely inhibited by the injection of a saturating amount of the other, 24 h before (R. A. Laskey and J. B. G., unpublished). These two quite different messages seem to compete for the same translational components, and seem to be little affected by message-specific factors. This system can be applied to messages of different cell types once these have been purified to a level where they can saturate an oocyte's translational system.

The injection of mRNA into oocytes has been able to demonstrate a specific effect of haemin on the translation of α -globin mRNA. The background to this experiment is that rabbit or mouse α -globin mRNA is translated about five times less efficiently than β -globin mRNA in oocytes and eggs of *Xenopus*, though the α and β -globin mRNAs are translated with about equal efficiencies in mammalian reticulocyte cell-free systems¹⁶. If globin mRNA is injected at a subsaturating concentration, the addition of haemin raises the efficiency of α -globin mRNA translation in oocytes so that it is equal to that of β -globin²⁴. This effect shows that haemin behaves as a message-specific translational factor in oocytes, and it may well do so in normal reticulocytes. It is of interest that this specific effect of haemin has not been revealed in cell-free systems²⁶.

Experiments involving the injection of DNA have given the, at first sight surprising, result that active DNA polymerase and other replicative enzymes are present and potentially active in egg cytoplasm, DNA synthesis being stimulated by the injection of DNA into enucleated eggs¹⁸. Apparently egg cytoplasm is provided with a large store of DNA replicating machinery which is provided for nuclei during their enormously rapid rate of division during cleavage, when each S phase is completed in 10 min and mitoses occur every 20 min²⁰. It may well be difficult for cleaving embryos, which have small numbers of cells and therefore of genes, to synthesise new messages for all the proteins which are needed in rapidly increasing amounts at this stage. Presumably this is why egg cytoplasm contains a large store not only of active DNA polymerases, but also of histones²⁷, tRNA²⁰, RNA polymerases²⁹, and ribosomes^{28,30}.

Wider application of injection experiments

Molecular biology in living cells is unlikely to be of wide interest if it is restricted for technical reasons to Amphibia which have the advantage of large eggs, but the disadvantage of a long (~1 yr) life cycle. The same technique can however be applied to genetically more felicitous organisms such as *Drosophila* which has an egg nearly 100 times smaller than that of *Xenopus*, and even to the eggs of mice, with a volume 4,000 times smaller than those of *Xenopus*. Yet fertilised mouse eggs can withstand the injection of 20×10^{-12} l of oil droplets³¹ and normal mice have been born from eggs injected with 10^4 molecules of polyoma DNA (J. D. Bromhall, C. F. Graham, J. B. G. and R. A. Laskey, unpublished). It is even possible to inject single cultured cells³²

but with not more than 5×10^{-15} l. Evidently most animal cells can tolerate the injection of at least a few per cent of their own volume, and the introduction of very large numbers of macromolecules not normally present. It is obviously desirable, however, to use amphibian eggs or oocytes whenever possible for such experiments.

Prospects

The experiments described here have been primarily aimed at demonstrating that at least some kinds of purified macromolecules can carry out their normal function after introduction into living cells. What are the long-term prospects for such experiments? Three are worth mentioning. First, an assay system is provided in which the regulatory role of purified macromolecules can be tested in a living cell. It is certain that no cell-free system which might otherwise serve this purpose can reproduce exactly the conditions which exist in a living cell and which are, in any case, not accurately known. Unless the haemin effect referred to above turns out to be exceptional, results obtained from cell-free systems may not give an accurate indication of what would emerge from experiments with living cells.

The second long-term use for introducing macromolecules into living cells is connected with 'rescue' experiments. The injection of purified regulatory molecules, as outlined in the last paragraph, is applicable only when such molecules can be collected in sufficient quantity to be purified. It is very likely, however, that cells make use of regulatory macromolecules which are present only in very small numbers and which have not yet been identified. An attractive procedure for identifying these was devised by Briggs and his colleagues³³, and involves the rescue of embryos which are genetically or experimentally deficient in development. The first successful rescue experiment³⁴ achieved the restoration of germ cell growth and fertility to *Rana pipiens* embryos which had been ultraviolet-irradiated to destroy the germ plasm, a region of egg cytoplasm which is needed for normal gamete differentiation. Subsequently, experiments were carried out with a maternal lethal mutant in the *Azotol* in which eggs laid by a homozygous mutant (%) always cease development at the late blastula stage (even if fertilised by wild-type sperm³⁵). Some of these lethal embryos were rescued by injecting them as eggs with wild-type egg cytoplasm, so that development proceeded normally for several days beyond the usual stage of arrest³⁶. Some progress has been made in determining the nature of the corrective component^{37,38}. Since developmental arrest is caused in such cases by a single mendelian factor, this design of experiment could lead to the identification of a gene product which plays an essential role in early development. The success of this approach, however, depends heavily on the assumption that the gene product in question can retain biological activity when injected as a purified preparation into egg cytoplasm. The results, summarised here, with injected proteins and nucleic acids certainly give some encouragement for the long-term success of such an

approach. Clearly the isolation of appropriate maternal lethal mutants poses a formidable problem, though some of these have now been isolated in the *Axolotl*³⁰, and *Pleurodeles*⁴⁰; in *Drosophila*, where several suitable mutants are known⁴¹, a rescue experiment has been carried out with *deep orange*⁴².

The third long term use of molecular injection experiments concerns the arrangement of molecules within cells. The asymmetric distribution of molecules has for long been believed to be a primary cause of the first regional differences in developing embryos, and may well be involved in later stages of cell differentiation as well⁴. When, in time, some of these unequally distributed molecules have been identified, it will be possible to deposit samples of them in one region of an egg or other cell type. If the injected molecules remain localised at the site of injection, this will show whether their unequal distribution is causally connected with the divergent cell differentiation that subsequently takes place. If, however, the injected molecules are rearranged within the cell, this will open the way towards an experimental analysis of the cause of the intracellular localisation. The experiences with histones, referred to above, show that at least some kinds of injected proteins can be rapidly redistributed in a cell so as to take up their normal intracellular location.

Building the Tower of Babble

Erwin Chargaff

Department of Biochemistry, College of Physicians and Surgeons, Columbia University, New York, New York 10032

In remembering, without nostalgia, the dawn of molecular biology, Dr Chargaff deplores the loss of innocence that science has suffered in his lifetime.

I

"Two weeks later," Watson writes in his book *The Double Helix*, "Chargaff and I glanced at each other in Paris. A trace of a sardonic smile was all the recognition I got when we passed in the courtyard . . . of the Sorbonne" (page 132). Unfortunately retaining, as I do, only the trivialities of my

past, I remember the incident at the Biochemistry Congress in 1952 and the gawky young figure, so reminiscent of one of the apprentice cobblers out of Nestor's *Lumpazivagabundus*. I felt far from sardonic: I was looking for a toilet; but whatever door I opened, there was a lecture room and the same large portrait of Cardinal Richelieu.

"Sarcastic" or "sardonic" are the attributes usually accorded me in that book. But what I really was, when I first met the fervid pair in Cambridge, was baffled, for here were two people trying to fit the nucleotides into a helix and

worrying about its pitch—it became a double helix, I believe, after I had told them about our results—without bothering to look up the structures of the compounds they wanted to fit together. My dismay before so much unimpeded boldness will be understandable only to those who consider that at this time molecular biology did not yet exist. In the meantime the sciences have learned that it is profitable to transgress their boundaries and to over-reach their competence. Somehow they swallow more than they have bitten off. So perhaps 'laconic' would have been a better attribute, for what I jotted down when I left Cambridge was: "Two pitchmen in search of a helix."

II

It is, however, not of Watson's book that I want to write here; I have done that before¹. What I should like to do is to sketch in a few words how it felt to get into science, and especially into the field of nucleic acids, in those prehistoric times (nwc), before revelations had begun coming down from the mountains; before the 'invisible colleges' had begun to play their disagreeable roles as restrictive guilds; and, for that matter, before *Nature* had begun to sprout those sprightly little *feuilletons*. In addition, I should like to say a few words about the way in which the present scene strikes me.

No one who entered science within the past 30 years or so can imagine how small the scientific establishment then was. The selection process operated mainly through a form of an initial vow of poverty. Apart from industrial employment, important for a few scientific disciplines, such as chemistry, there were few university posts, and they were mostly ill-paid. One of my former chiefs at that time assured me that for him the opportunity of doing research as he pleased was sufficient recompense. (He had, besides, a comfortable private income.)

Science—or at any rate that part of science with which I am familiar—was small; it was cheap; it was wide open. One could still do experiments in the old fashioned sense of the word. Now, everybody is working away at 'projects' the outcome of which must be known in advance, since otherwise the inordinate financial investment could not be justified. Papers, however, continue being written in the old way, as if the discovery had come after the search. The number of very significant scientific discoveries made in the interval between the two world wars was truly enormous. The impulse persisted, or even increased, in the United States up to about 1950 or 1955, and then slackened perceptibly, almost in reverse proportion to the number of new scientists entering the several disciplines. I know of few instances in which the dialectical change of quantity into quality has been so obvious.

Since at that time it cost relatively little to perform scientific experiments, it was always possible and even inviting to venture into fresh areas. The risk was minimal and so, unfortunately, sometimes were the results. But the road to them was always delightful. This changed gradually as a result of several powerful technological advances. The introduction of isotopic labels gave rise to an industry whose products became increasingly more expensive, as the variety of the compounds grew and purity standards declined. The construction of powerful centrifuges and other physical equipment extended immensely the range of the possible, but even more the cost of achieving it. Other advances, especially in chromatography, electrophoresis, and spectrophotometry, contributed more than they took away. Still, it remains that according to my highly unreliable estimate a current paper of mine costs about 20 to 25 times more to produce than an equivalent article 35 years ago, if such things can be weighed and compared. The argument that such calculations are meaningless—for what would we give if we had one more Mozart opera—can be rejected; none of us writes Mozart operas.

III

The small number of scientific workers engaged in research had other consequences. It was easy to open new fields and to go on cultivating them; there was no fear of immediate dispossession as is bound to happen now. There were relatively few symposia, and those that existed were not attended almost exclusively by hungry locusts yearning for fields to invade. Bibliographies were comparatively honest, whereas now entire packages of references are being lifted by a form of transduction, as it were, from one paper to the next; so that if some work gets into the habit of not being quoted, it never will be so again. The break in the continuity of the tradition has, perhaps, been one of the most disastrous effects of the scientific mass society in which we are living now.

The illusion that what is new is true has distorted the very sense of scientific research. The urge to be 'with it' is incompatible with the search for truth about nature—and that is what science is—and where one can say 'this is no longer true,' nothing is true. Some years ago, I heard an eminent colleague declare at a congress: "The results that I reported last year were based on facts that are no longer available"—a form of recantation that should have delighted Galilei without offending the Inquisition. Our current literature is brimming with facts, but many, I am afraid, are no longer available. If the vaunted self-purification of science has broken down some time ago, this is only in part a result of the ever increasing complexity of ever more poorly described experiments. It is even more a consequence of the pressed and driven mood in which research often is performed now: "... in a hurry of waste, and haste, and glare, and gloss, and glitter."²

Two more points will complete this hasty sketch of a Golden Age that never was. As the number of scientists was so small, it was easy for a young man to establish himself. Two or three decent papers, and he was in, for what it was worth. Another consequence of the restricted dimensions of our scientific knowledge at that time, before it was overwhelmed by multiple massive explosions of facts, many of them of the utmost triviality, was that it was still possible to comprehend the essentials of one or even of several sciences. This bucolic security has, I believe, ended: "out of swimmers we have all turned into floaters."³ Or, to put it less metaphorically: "the sciences, like other professions, cannot endure if their practitioners are unable to know more than an ever-smaller portion of what they must know in order to function properly."⁴ Even granting all the present difficulties in acquiring sufficient knowledge, I must say that the extreme dislike, and therefore ignorance, of chemistry I have often encountered among molecular biologists is puzzling. Chemistry is the science of substances; and to the extent that molecular biology deals with substances and not in them, as if they were commodities, a thorough acquaintance with chemistry is advisable.

IV

I should be sorry if I give the impression that I am trying to paint an *aurea aetas*. I grew up in bestial times, and they have become worse. I have written elsewhere of my surprise that such bad times gave rise to so much good science^{5,6}; probably the only activity of the human mind that has, until recently, been in the ascendant. It is, however, not astonishing that in a rotten society even the saints will carry a slight aroma of rottenness.

One of the outstanding curses of my lifetime has been the manipulation of mankind by advertising and propaganda. In the sciences this evil force had for a long time remained unnoticeable, perhaps because expanding capitalism and youthful imperialism had other worries, perhaps because scientists owing to their small number survived unharmed in the crevices of a society that still paid little attention to

them. The first figure of the highest rank that I saw being lifted by the wheels of the publicity machine and turned into a celebrity was Einstein. (Einstein's very interesting correspondence with Max Born and with Mrs Born displays many instances of this process; compare, for instance, the letters of October 7 and 13, 1920, pages 62 and 65.) Freud, who could have been another victim, escaped the glare entirely, being 23 years older. He also benefited from the fact that his discoveries were relatively accessible: an element of impenetrability helps. There may have been before my time another instance of mindless acclaim, namely, in the case of the Curies and the discovery of radium, to judge at any rate from the slightly paranoiac image reflected in Strindberg's *Blue Books*; but then one could hardly yet have spoken of the mass media.

When molecular biology appeared on the scene, however, the publicity machines were all in position and it was time for the saturnalia to begin in full force.

V

I should not want to leave the impression that molecular biology began with the double helix. The reason, and even the date, of the appearance of sectarian movements is hard to determine. I have, in another article, attempted to delineate its pedigree which probably had its origin in the discovery of the transforming properties of DNA and the introduction of bacteriophages as objects of biological research^{5,6}. In my opinion, there really was little sense in creating a new science that consisted essentially in the application of chemistry, and to a limited extent of physics, to biology; that is what biochemistry and biophysics stand for.

I remember vividly my first impression when I saw the two notes on DNA that appeared in *Nature* 21 years ago^{8,9}. The tone was certainly unusual: somehow oracular and imperious, almost decalogous. Difficulties, such as the even now not well-understood manner of unwinding the huge bihelical structures under the conditions of the living cell, were brushed aside, in the Mr Fix-it spirit that was later to become so evident in our scientific literature. It was the same spirit that soon after brought us the 'Central Dogma' to which I believe I was the first to register my objection, never having been very fond of gurus with a PhD. I could see that this was the dawn of something new: a sort of normative biology that commanded nature to behave in accordance with the models.

The structural model proposed for DNA in the first note⁸, a helical dyad held together by base pairing, seemed to me not only an aesthetically pleasing solution, but also the most plausible inference from the base-pairing regularities earlier discovered by us in many DNA preparations¹⁰. I was much less in agreement with the scheme for DNA replication proposed in the second note⁹; and even now, 20 years and thousands of experiments later, I cannot say that I am reconciled with it completely, the mechanism of DNA synthesis *in vivo* still being obscure to me.

I do not know whether in 1865, when Kekulé put forward the structural model of benzene, which was to revolutionise organic chemistry, neckties appeared forthwith, embroidered with the pretty hexagons. I should rather doubt it, since at that time mass cretinisation had not yet begun and advertising still was a home industry. At any rate, the publicity carnival that ensued upon the unveiling of the DNA model was probably unique in the history of science. I have given a brief description in my Bertner Foundation Award Lecture¹¹.

VI

Scientific induction is actually the resultant of a parallelogram of rational and irrational forces. That is why in many respects Science is not a science, it is an art. The importance

for scientific research of imagination, of unpredictable conclusions from unexpected analogies, can, therefore, not be overestimated. If all can be declared in advance, then there remains only the dull verification. The greater the reliance on axiomatic constructions, on prescriptive models must be, the more restricted becomes the freedom of the scientific intellect, the narrower is the range of what can be discovered. These are, I am afraid, the conditions under which a great part of molecular biology now operates.

Research always runs the danger of overasserting the truth of its observations, leaving even less space for dialectics to turn around. For me, however, scientific truth consists of what has not yet been disproved; it is at best a dense mosaic of approximations. Therefore the chase is worth so much more than the prey; or, to put it less violently, the road counts more than the destination. Do I hereby propose Sisyphus as the patron saint of the scientist? Not in a general way. What was tragic about the fate of this mythological celebrity was that he was always lifting and losing the same rock; which is, indeed, what many molecular biologists are now doing.

Many of the papers in this field are very competent technically. Since the same procedures are used, regardless of the particular biological system investigated, the results usually confirm each other; and this is taken to prove the unity of nature. When novel apparatus and techniques are introduced, a new set of results is obtained; and this is registered as scientific progress. A pall of monotony has descended on what used to be the liveliest and most attractive of all scientific professions. The noble study of botany, for instance, has been all but banished from many universities. Before, the biological sciences had each their characteristic faces and their distinct spheres of interest into which they drew different types of scientists. Now, when I go through a laboratory, be it of virology or of developmental physiology, there they all sit before the same high-speed centrifuges or scintillation counters producing the same superposable graphs. There has been very little room left for the all-important play of scientific imagination. *Homo ludens* has been overcome by the seriousness of corporate finances.

VII

Our period, just because it is altogether so weak intellectually, is given to extraordinarily strong assertions. Many of the great constructions of our time—existentialism, structuralism, transformational grammar, the central dogma and some other sloganised tenets of molecular biology—have all looked, from their very beginning, somehow shoddy and overblown. There was about them a flavour of not being entirely earned, as of trick images viewed in a mirror. As the mirror clouded over, the images vanished. Much of what they claimed may actually have been true; but they looked like packages much too large for what they contained. One got the impression that it was often the wrapping that produced the particular content; just as there are now packaging artists who wrap entire mountains in plastic flimsy.

This is not the note, however, on which I wish to end. I should like to recall a few names. They are the names of those who had done some of the basic work on nucleic acids and whom I got to know personally, either before or after I left sweeter fields to concern myself with the harsh problems of nucleic acid chemistry. T. B. Johnson, of Yale University, who got me first to America, did some of the most important work on the chemistry of the purines and pyrimidines. Steudel, once one of Kossel's collaborators, I met at the University of Berlin. Alexander Todd showed me through the organic chemistry laboratories when I visited Oxford in 1934. I often saw P. A. Levene at the Rockefeller Institute; his work, especially on the sugar constituents of the nucleic acids, deserves more admiration than it now receives. At

the same institute I sometimes got a glimpse of the great and modest Avery. And there were Gulland and Jordan and J. N. Davidson, Brachet and Caspersson, Bawden and Pirie, Hammarsten and Jorpes, Thannhauser and Gerhard Schmidt, Mirsky and Pollister, and the gentle and courteous Belozersky in Moscow. Zacharias Dische, without whose diphenylamine reaction most of the work on DNA could not have been performed, has for years been a colleague at Columbia University. Many of these men have gone, but the list is, luckily, not entirely sepulchral. They all did their work before the strip-mining of nature had become so prevalent, before researchers had become alienated from the objects of their study. In the tower of forlornness, which the House of Science has become in my time, the inhabitants all speak the same language, but do not understand each other.

Few will be of my opinion, certainly not the one who made fun of me some time ago in a magazine article, saying

that my ideal of a scientist was Louis Pasteur played by Paul Muni. This may be so, though I doubt it. What I do dislike, however, is to see *E. coli* impersonating nature. The difference in talents is really too great.

Molecular biology and metaphysics

Gunther S. Stent

Department of Molecular Biology, University of California, Berkeley, California 94720

"And now the announcement of Watson and Crick about DNA. This is for me the real proof of the existence of God". (Salvador Dali, 1964).

FRANCIS Crick prefaces his 1966 John Danz Lecture *The Nature of Vitalism*¹ with this quotation from Dali, but mentions neither the surrealist painter nor God in the body of his text. Why, then, does Crick quote Dali? As readers of *The Double Helix* know, James Watson has "never seen Francis Crick in a modest mood". But not even Watson would claim that Crick really believes that they have delivered the final proof for the existence of God. No, my friend Crick finds Dali's statement a tremendous joke and though Dali's intent was surely serious, Crick is making fun of him by according Dali the place of honour under the masthead of an antireligious tract. But I think Dali has sized up the situation quite correctly: the achievements of molecular biology have furnished proof for the existence of God. And that, as I shall try to show here, could be bad news.

To begin, I draw attention to the fact, long appreciated by philosophers, that science rests on metaphysics. That is to say, the attempt of science to explain the world is based on a set of *a priori* beliefs whose validity cannot itself be the subject of scientific enquiry. Now that the once-fashionable philosophy of positivism (which threw metaphysics into the philosophical ashcan) is all but moribund, it should hardly be necessary to belabour this point. But since in *Chance and Necessity*², the best known philosophical book by a molecular biologist, Jacques Monod holds fast to the 17th century empiricist notion of a science free of subjective projections into nature, which Kant had laid to rest nearly 200 years ago, a reminder of the transcendental basis of science may not be out of place.

Platonic doctrine

One of the most fundamental of the *a priori* beliefs that makes science possible is Plato's monistic doctrine of a single principle that not only regulates the course of the sun and the stars but also prescribes to all creatures their proper behaviour. That single principle is God, or his atheistic synonym, Eternal Reason, whose power, according to Isaiah Berlin, "has endowed all things and creatures each with a

specific function; these functions are elements in a single harmonious whole and are intelligible in terms of it alone. . . . This unifying monistic pattern is at the very heart of traditional rationalism, religious and atheistic, metaphysical and scientific, transcendental and naturalistic, which has been characteristic of Western civilization. It is this rock upon which Western beliefs and lives have been founded. . . .³ Thus belief in God is not only not incompatible with rational thought but it is the metaphysical axiom from which it follows that an explanation of the world is accessible to human reason. This accessibility is, in turn, provided for by the existence of God-given Natural Law that governs the orderly operation of the world. Thus a scientist is a man who believes in God, for without this belief it would be futile to try to discover His Laws.

I will document this allegation, which the majority of contemporary scientists surely reject, by quasi-humorous citations from two great scientists, since according to Freud, jokes reveal repressed thought⁴. First, in his Danz Lecture, Francis Crick points out that though the three-dimensional conformation of proteins can, in principle, be worked out from the structure of their component amino acids, the necessary computations are almost prohibitively long. But proteins find their conformations all the same because "Nature's own analogue computer—the system itself—works so fantastically fast. Also she knows the rules more precisely than we do. But we still hope, if not to beat her at her game, at least to understand her". Second, as is well known, Einstein affirmed his unwillingness to accept the epistemological implications of Heisenberg's Uncertainty Principle by saying that "God does not play at dice". By these statements, Crick and Einstein reveal their allegiance to the Platonic doctrine, and Crick probably makes the verbal substitution of a personified 'Nature' for 'God' only to avoid giving the impression that he is a Christian.

The application of the Platonic doctrine is not limited to science, of course, but also provides the foundation for Western ethics. These ethics, held by Judeo-Christians and Western atheists alike, envisage the existence for their own sake, of objectively valid, ultimate values of right and wrong. It is because of the recognition of these God-given (or 'natural') values that we can speak of crimes, or morally justify or condemn any act. But as Berlin points out, there is also another system of ethics, which Berlin terms 'pagan'

and which derives its authority, not from God but from the obvious fact that man is a social animal who lives in communities. In the pagan system there are no ultimate values, no intrinsic rights or wrongs, only communal purpose, and so moral judgements here are relative rather than absolute. Since, our adherence to the Platonic ideal notwithstanding, we cannot ignore the pagan reality, the ensemble of Western aims and values is internally inconsistent. Berlin credits Machiavelli with the discovery of this fact and with showing "that the belief that the correct, objectively valid, solution to the question of how men should live can in principle be discovered is itself in principle, not true". According to Berlin, it is for having split open the Platonic rock upon which Western lives are founded, for pointing out the impossibility of the City of God, rather than for being 'Machiavellian', that Machiavelli has drawn an ecumenical and everlasting hatred from men representing the whole spectrum of Western religious, philosophical and political thought.

Western contradictions

What can be done to resolve this contradiction in Western lives? Admittedly, in the ethical domain one may reasonably doubt whether grafting the lofty ultimate values of Judeo-Christianity on pagan down-to-earth ethics has really been a good thing. But in the scientific domain the notion of Natural Law has evidently been gloriously successful. Particularly since Galileo, modern science has gone a long way in showing that reason can explain the world and that by the understanding thus obtained one can gain mastery over Nature. So how can we give up our Platonic legacy and return to uncorrupted paganism? It is in this light that we must view the triumph of molecular biology over vitalism that both Crick and Monod celebrate in their essays.

Crick has "a strong suspicion that it is the Christians, and the Catholics in particular, who write as vitalists, and it is the agnostics and atheists who are antivitalists". Crick may be right in his suspicions, but I see no philosophical or theological connection between Christianity and vitalism. On the contrary, in so far as vitalism boils down to the proposition that a full explanation of life is beyond the capacity of the human intellect, it subverts the Platonic doctrine. By questioning the accessibility of the world to reason, vitalism raises doubts about the existence of God as the author of Natural Law. Accordingly, the writings of the Jesuit Teilhard de Chardin, a source of inspiration for many latter-day vitalists, were considered heretical by his superiors in the Society of Jesus and suppressed by them. Thus, as long as Schrödinger's query "What is Life?"⁵ had not been answered and as long as science had not been able to account for the basic processes that distinguish living matter from dead, there still seemed a chance that life is not God's handiwork after all. But as Dali recognised, now that molecular biology has shown how life can be explained in terms of ordinary physics and chemistry, further proof has been delivered that God designed the world and saw to it that His plans are comprehensible to man. In other words, by contributing to the validation of the monistic doctrine, Watson and Crick have made it more difficult for Western man to get off his Platonic rock.

The achievements of contemporary biology have helped to bring to light the moral contradictions inherent in the Western ethical system. To appreciate the nature of these contradictions we must consider the concept that is altogether central to that system, namely the soul⁶. Belief in the soul has been as essential for Western ethics as belief in Natural Law has been for Western science. As is well known, the modern formulation of the problem of the soul is due to Descartes, who laid the philosophical foundations for physiology, and thus also for molecular biology, by advancing the fruitful notion that the bodies of humans and animals can be regarded as machines. But since moral principles

obviously do not apply to machines and do apply to humans, humans must be more than automata in human shape. The extra something that makes humans more than automata is the soul. It is from his incorporeal soul that man derives both the freedom of and the responsibility for action, without belief in which there can be no morality. For dealing with the intersection of morals and human biology, nothing has thus far replaced the Cartesian body-soul dualism. Admittedly, as Crick points out, "many scientists believe that the soul is imaginary and that what we call our minds is simply a way of talking about the function of our brains". But in denying their belief in the soul, these scientists, in so far as they are moral beings, merely resemble Molière's Monsieur Jourdain, who did not realise that he was speaking prose. It must be noted that Monod is not one of these scientists, since he devotes a major part of *Chance and Necessity* to showing just why what he calls "the modern soul" is in distress.

Mental illness

Consideration of two examples of a contemporary conflict between biology and morals show that this conflict arises from the impossibility of resolving the body-soul dualism. One of these examples is provided by radical criticism directed against the treatment of the insane, indeed against the very concept of insanity. In an essay, *Mental Illness as a Metaphor*⁷, Thomas S. Szasz, himself a professor of psychiatry, argues that mental illnesses are not genuine diseases and that psychiatry is not a *bona fide* medical specialty. One of the two main arguments put forward by Szasz in support of this claim is that a medical patient can only be a person who voluntarily assumes that role and a physician can only be a person who gives treatment with the consent of his patient. Since according to Szasz, psychiatric treatment is, more often than not, involuntary, insane persons are not really ill and psychiatrists are not really physicians. Thus psychiatric practice maintains not health but law and order, and does so in a manner which is incompatible with the ideals of a free and just society. Szasz' other main argument is that insanity is not attributable to "an abnormality or malfunctioning of [the] body. . . . Strictly speaking. . . . disease and illness can affect only the body. Hence there can be no such thing as mental illness. The term 'mental illness' is a metaphor". Thus, in contrast to Crick's "many scientists" who believe "that what we call our minds is simply a way of talking about the function of our brains", Szasz has recognised the unacceptable moral consequences of that belief. It is a "systematic strategy . . . for stigmatizing and depersonalizing persons". Evidently, Szasz is informed by the notion that the "real" person, the free and responsible agency, is not the body but the incorporeal soul. Thus, to treat insane people as if they were sick is, according to Szasz, to confuse medicine with morals. In other words, the biological reification of the soul, the dissolution of the Cartesian dualism, is incompatible with the maintenance of Western ethics.

Genetic engineering

The second example of a contemporary conflict between biology and morals is provided by the imminent extension of 'genetic engineering' to humans. Though the proponents of a deliberate manipulation of man's genotype intend it in all sincerity to augment human welfare, this prospect is generally viewed with extreme distaste, and not only by the righteous guardians of so-called 'social responsibility' in science. Why should an application of the fruits of biological research of overt philanthropic intent, which is not meant to kill defenceless civilians, exploit subject peoples, or despoil the Earth, nevertheless evoke the spectre of Dr Strangelove? To fathom the root of this problem we may consider a

fantastic facet of genetic engineering which, though it seems taken straight from the pages of Aldous Huxley's *Brave New World*, is actually likely to become a practical reality before long. This is the asexual reproduction, or cloning of humans by transfer of somatic diploid nuclei from a male or female donor to enucleated eggs. Out of such eggs can develop a clone of genetically identical individuals, all of exactly the same hereditary constitution as the donor. This technique will soon make it feasible to abandon the old-fashioned genetic roulette of sexual reproduction and start populating the Earth with identical replicas of carefully chosen, ideal human genotypes. As far as I know, no one has actually come forward to advocate the institution of this programme, even though from a eugenic point of view, it offers tremendous possibilities. Evidently, the idea of cloning humans is morally and aesthetically completely unacceptable. But why is it that whereas it would be fun to have Kant, Beethoven, Isadora Duncan, Einstein, Clark Gable and Marilyn Monroe living on your block, the thought of having hundreds or thousands of their replicas in town is a nightmare? The reason for this horror is the generally shared belief in the uniqueness of the soul. Even though the soul is incorporeal, it is supposed to fit the body, and hence it is not conceivable that a unique soul inhabits each of thousands of identical bodies. In other words, a human clone would not consist of real persons but merely of Cartesian automata in human shape.

To oppose human cloning, however, is to betray the Western dream of the City of God. All utopian visionaries, from Thomas More to Karl Marx, think of their perfect societies as being populated not by men but by angels that embody all of the best and none of the worst human attributes. As long as, due to the vagaries of the sexual reproductive mode, there was not the slightest chance that such angelic populations could actually arise, this seemed like a believable dream, a hope for the future. But now, when advances in molecular and developmental biology have brought asexual generation of homogenous populations selected for angelic properties within practical reach, it suddenly becomes clear that this is not the perfect society that is wanted after all. What is wanted is the impossible: a perfect society made up of a motley collection of imperfect, unique souls, warts and all.

Chinese alternatives

These conflicts are unlikely to be resolved within the context of the Western tradition. What it would take to remove them from Western lives is to abandon belief in God, His ultimate values and His Natural Law. But is it possible to run a civilised society on purely pagan metaphysics? It certainly is, since another great civilisation, the Chinese, has operated for millennia on just that basis. Chinese lives are not founded on the Platonic rock that Machiavelli split open and when viewed in the light of the Chinese tradition, Western scientific atheism is merely old divine wine in new bottles. Just about the time when the Platonic doctrine was formalised in Greece there developed in China the two complementary philosophical-ethical systems of Taoism and Confucianism which have governed life in the Middle Kingdom ever since. The precepts of Confucianism are based on the premise that man is a social creature and that therefore there is virtue in harmonious social relations. These relations are made harmonious not by obedience to universally valid abstract moral principles but by exact adherence to a combination of prescribed etiquette and ritual. Taoism, is a transcendental moral philosophy whose main relevance is for the inner life rather than for social relations. Its precepts are based on the belief that man is part of (non-personalised) Nature and that, therefore, his life must take the path, or *tao*, of natural events. Man, following the *tao*, must abjure all striving,

distrust reason, and attempt to attain a state in which he is as free from desire and sensory experiences as possible. Neither Confucianism nor Taoism invokes God or Eternal Reason as the source of its authority, nor do they posit the existence of Natural Law or ultimate values. Rather, both systems endeavour to provide for man's harmony with his environment.

In my opinion it is highly significant that Chinese attitudes are now coming to exert an ever-growing influence in the West. This influence is no longer confined, as it was only a few years ago, to Zen Beatniks, New Left Maoists, transcendental meditation freaks and other far-out members of the Counterculture. Instead, it has reached the very Pillars of Society. For instance, the recent, mainly middle-class, interest in 'ecology' is a radical departure from the ancient Western aim of dominating Nature. It is nothing less than a Taoist subversion of the hallowed 19th century belief in progress. Similarly, the recent accommodation of the two Superpowers, the United States and the Soviet Union, and the ending of the quarter-century-long Cold War, suddenly abandons, without any profound political change in either country, the righteous reciprocal Crusade to smite the Anti-christ or Enemy of Man. It constitutes a Confucian subversion of the Western romantic ethic of the Nation as the Protector of the True Faith and places harmony above ideology in international relations.

Another important consequence of the Sinification of the West is the recent, and for most old-time scientists quite incomprehensible, loss of faith in the 16th century creed of Francis Bacon that the discoveries of science ameliorate the human condition. More and more people have come to embrace the belief that what it will take to save the world is not to build a better mousetrap but to understand man. But with this development we are reaching the limits of biology: whereas its methods are evidently capable of giving a satisfactory account of human physiology, human psychology does not seem to be accessible to the procedures discovered by Galileo. This conclusion follows from the growing ascendancy of the 'structuralist' over the 'behaviourist' approach to the study of human behaviour. Behaviourism, whose working methods are more or less those of modern science and whose propositions are therefore subject to validation, has thus far produced mainly trivialities. Structuralism, on the other hand, particularly as pioneered by Freud, has offered some deep insights. But structuralist methodology, and its central theoretical axiom that the causal relations governing overt behaviour occur between covert 'deep' mental events whose existence can be inferred only indirectly, renders scientific validation of these insights well-nigh impossible.

Thus the metaphysical implications of modern biology are not quite what my friends make them out to be. It is not the triumph of molecular biology over vitalism that has made belief in God unnecessary. Rather, it is the apparent inaccessibility of the human psyche to scientific study and the prospect that psychoanalysis (which Crick regards as "mental bleeding") may be the best we can do that still leaves open the possibility of abandoning Him. Therefore, not because of but despite "the announcement of Watson and Crick about DNA", the West may still remain free to descend from its Platonic rock and join the East in a pagan One World.

DNA before Watson—Crick

Robert Olby

Department of Philosophy, University of Leeds, Leeds LS2 9JT

"Nucleic acids bulk so large in the composition of cells that it seems certain that these substances are involved in some important biological functions. Nevertheless, with one exception [bacterial transformation], there has been no proof of a specific biological function mediated by one of these polynucleotides; no enzyme, hormone, vitamin, or even vague 'growth substance' has been found to be a nucleic acid."

WITH these words Pollister, Swift and Alfert introduced their work on the metabolism of DNA to a conference on the biochemistry of nucleic acids, held at Oak Ridge in April 1950. Their paper furnishes the historian with clear evidence that by this date DNA was receiving serious consideration as a major component of the hereditary code-script, quite independently of the work on the biology of bacteriophages and on the base composition of DNAs. When Watson and Crick turned to the structure of DNA they knew it was a macromolecular compound, a major constituent of the sperm nucleus, phage head, and chromosome. They could not but be aware of the association between the staining properties of chromatin and of DNA. Only extreme ignorance would have prevented them from knowing of the correlation between chromosome duplication and the synthesis of DNA. Add to these facts the proven identity of the transforming principle with DNA, and one is presented with compelling reasons for identifying DNA with the genetic substance in October 1951 when Watson came to Cambridge and began his collaboration with Crick. Or is the situation only seen as compelling with the aid of hindsight? We must recall that the earlier decision against the genetic role of DNA had to be overcome. It was not so easy in the 1940s as it may seem now to transfer the onus for proof of genetic function from DNA to protein. On what grounds had the candidacy of DNA been rejected and how was the evidence, so damaging to DNA, undermined?

Looking for the hereditary substance

At the end of his life the Swiss physiologist, Fritz Miescher, arrived at the figure of 80% for the nucleoprotein content of the sperm head. His results were reinterpreted by Oswald Schmiederberg who gave the figure of 96% (ref. 2). Those who accepted that hereditary transmission is due to chemical compounds were therefore anxious to discover in nucleic acids and protamines evidence of chemical differences. They looked for metabolic stability and for continuity from one cell generation to another, but they did not find it! Miescher doubted the importance of nucleoprotein. He had high hopes of a mysterious iron-containing compound which he called "karyogen" supposedly located in the centre of the sperm head, where it was wrapped around with nucleoprotein. His successors, Burian, Mathew, Boveri, Loeb and Strasburger were by no means convinced that either nucleic acid or protamine constituted the hereditary substance. Even the American cytologist, E. B. Wilson, often cited as a supporter of the DNA theory of the gene, in fact identified the genetic substance as 'nuclein', a chemical

compound of nucleic acid and protein. Some authorities regarded mere chemical compounds inadequate for hereditary transmission and invoked 'higher' morphological structures. In this they were supported by the supposed discovery of a cycle of loss and recharging of the chromosomes with nucleic acid. When the cell divided, the chromosomes became short and fat; they took up basic stains avidly and showed up clearly under the microscope. After division these same chromosomes elongated and their power to attract basic stains weakened. The staining substance—chromatin—or DNA, was not, it seemed, the stable continuing genetic material. This must be "achromatin", possibly the protein fraction of the chromosome.

In the sperm head, protein was present in the form of rather specialised compounds known as "protamines". They were found to be much simpler in their composition than any other class of proteins, some having as much as 87% by weight of one amino acid, arginine. Moreover, no continuity could be traced between them and the histone-type of protein of normal body cells. Yet this did not dissuade some biochemists from seeking genetic specificity in the protamines. Thus in 1935 Waldschmidt-Leitz saw the structural comparisons of protamines as preparing "the ground for a chemical investigation of problems of heredity"³. In 1950 K. Felix in Strasbourg was applying paper chromatography to the protamines to determine the quantities of the six mono-amino acids which made up one tenth by weight of the fish protamine, clupein⁴. In 1952 his study of the breakdown products of clupein gave over one-third in the form of four arginine residues strung together, surely reason enough to pass some adverse comment on the potential variety of protamine molecules? No such remark was made⁵.

Others, doubting the potential of both nucleic acids and protamines, searched for other compounds in nuclei. Edgar and Ellen Stedman found only 70% of the sperm head in the form of nucleoprotein; the remaining 30% they attributed to proteins higher than the protamines and histones, which they called 'chromosomin'. This, they claimed was a group of proteins, the amino acid content of which differed from species to species. Now they could overcome the failure of chemistry to provide the required chemical differences by identifying the hereditary materials with chromosomin. Nucleoprotein was no more than a constituent of nuclear sap! To be sure it was condensed on the chromosomes dur-

TABLE 1 Base analyses of nucleic acids from 1902 to 1950

Date	Molar ratios				Authors	Nucleic Acid
	A	G	C	T/U		
1902	1.0(?)	0.98	—	1.17	Osborne and Harris	RNA
1905	0.47	0.23	1.35	1.0	Levene	DNA
1906	1.30	0.98	0.63	1.09	Steudel	DNA

1950	0.29	0.18	0.18	0.31	Chargaff	DNA

FIG. 1 The tetranucleotide according to Levene.

ing certain phases in the nuclear cycle—as in the sperm head—but this was a transitory state of affairs⁹.

In 1946 Mirsky and Pollister applied their salt extraction technique to trout sperm. The nucleoprotein content of the sperm head came to 91%, leaving 9% of what they called a 'residual protein'. This was distinct from protamine, and like chromosomin, it seemed a promising candidate for the hereditary substance. Not until 1951 did Felix put his authority clearly behind the conclusion that the head of the sperm contains only nucleoprotamine⁸. This search for a residual protein indicates that DNA itself was unacceptable as the genetic material. Although the achromatin hypothesis played a part in achieving this situation it was the tetranucleotide hypothesis which increasingly threw DNA into the shade.

The tetranucleotide hypothesis (or theory as Levene called it) asserted that DNA and RNA had a molecular weight of about 1,300, and contained one of each of the four bases (adenine, guanine, cytosine and thymine in DNA; adenine, guanine, cytosine and uracil in RNA). Because these bases were found to be present in the form of nucleotides (sugar-phosphate + base) the molecule was called a tetranucleotide. Early analyses had shown there to be four phosphorus atoms per molecule, and when four bases were discovered in DNA it was natural to hope to find them in equimolar proportions. The fact that base analyses (see Table 1) deviated by as much as 54% from expectation, and were not always complete, did not trouble these investigators. They had a difficult task on their hands; powerful methods were needed to split the molecule, and bases were easily lost or altered. Osborne and Harris began the tradition of equimolar proportions; Steudel extended it and Levene established it. In the process he twice quoted the figures which Steudel had predicted from the tetranucleotide as his experimental results! Since Levene identified esters of the pyrimidines with two phosphoryl groups attached to them in the breakdown products of DNA he developed an argument for the alternating sequence—pyrimidine, purine, pyrimidine, purine—and rejected any other arrangement. Arguments such as this depended, of course, on the assumption that DNA was a small molecule.

Yet the tetranucleotide hypothesis was not swept away once the macromolecular nature of DNA became established in the 1940s. Doubtless this was to a large extent a case of the entrenchment of a theory. In part it must also have been due to the great success of the theory, for it represented the conclusion of Levene's brilliant work on the constitution of nucleic acids. Out of a confusion of erroneous and vague ideas he had extricated a clear concept—the equimolar proportions of the bases—and built upon it the model of the nucleotide which by sugar-phosphate linkage gave the same chain structure that we accept today (Fig. 1). This hypothesis was, then, a remarkable case of a paradigm which started off as a work-

ing hypothesis, gained explanatory power when associated with the nucleotides, and became so rooted in the chemical thought of nucleic acid chemistry that a revolution was required to overthrow it.

Early estimates of the molecular weight of DNA were based on percentage composition, but although this yielded only the minimum value, it was universally taken to be the true molecular weight—about 1,300. In the nineteenth century Miescher had shown DNA to be a slowly diffusing compound, and Neumann had perceived the distinction between an extract of DNA which readily formed a gel and one which did not. The latter, he thought, resulted from the depolymerisation of the former. But as Fig. 2 shows it was not until 1938 that the macromolecular nature of DNA was demonstrated by Caspersson and the Hammarstens⁹. Levene then obtained crude extracts of the depolymerising enzyme, DNase, and confirmed the Swedes' work. Did he then denounce the tetranucleotide hypothesis?—No! In 1931 he had conceded the possibility that DNA might be a multiple of the tetranucleotide, and in 1938 he was still considering the possibility of depolymerising the macromolecule right down to "a single tetranucleotide"^{10,11}. Nor was he alone in this. The great German nucleic acid chemist, Robert Feulgen, was also convinced that depolymerisation yielded a product with the tetranucleotide structure¹². Even Gulland accepted the polytetranucleotide as a working hypothesis in 1944, but thought better of it a year later and introduced the 'statistical tetranucleotide' to describe a polynucleotide with base composition equal to that for a tetranucleotide, but with a 'random' sequence^{13,14}.

The clearest evidence for the tetranucleotide, it had seemed, was the supposed existence of one secondary phosphoryl group for every four primary groups (Fig. 1). Only by assuming a four-membered chain could the ratio of 1:4 be explained. If DNA was a very long chain this old titration data of Levene's school must have been wrong, or the DNA studied must have been degraded. Gulland and his colleagues at Nottingham repeated these electrometric titrations and found an "almost entire lack of secondary phosphoryl dissociation"¹⁵. This work was published in a symposium of the Society for Experimental Biology in 1947. It was widely read with the result that attempts were made to improve extractive procedures and prevent the action of DNase. This in turn yielded less degraded DNA from which it was possible to obtain good X-ray diffraction patterns.

Bacterial transformation by DNA

The overriding claim of the proteins to be the hereditary substance rested on the demonstration of their biological specificity in enzymes, antigens, hormones, and viruses. The discovery of nucleic acid in the latter did not alter the situation, since no differences between the nucleic acids of different virus strains could be detected. Therefore, the claim of Avery, MacLeod and McCarty in 1944¹⁶ that DNA can cause a specific heritable alteration to a bacterium found no support from experiments in any other quarter. Nevertheless, this work was not neglected, unknown, undiscussed. On the contrary it sparked off several important researches. These led to the discovery of base ratios and the Boivin—Vendrelly rule.

The first to claim that bacterial transformation was achieved by DNA in another bacterium was the French scientist, André Boivin. Although subsequent attempts to repeat his work failed for many years (until 1972), many scientists were impressed by his work. It led him to seek for features in the metabolism of DNA that one would expect of the hereditary material—that germ cells should have half as much DNA as the body cells since their chromosome number is halved. In 1948 Boivin, with his colleagues, the Vendrellys, was able to announce a halving from 6.5×10^{-6} daltons to 3.4×10^{-6}

FIG. 2 Molecular weight estimates of DNA. The highest value comes from *Drosophila* DNA; see *Chromosoma*, 48, 1 (1973).

daltons (ref. 17). The significance of this halving rule (the Boivin-Vendrelly rule) was brought out by parallel studies of the metabolic turnover of DNA.

Since 1943 the studies of radioactive incorporation of ^{32}P by Hevesy and his colleagues in Sweden had made plain the contrast between DNA and other cellular compounds, including RNA¹⁸. Its turnover was but a fraction of the others. Also N. J. Davidson, at St. Thomas' Hospital, London, tried starving rats of protein for two days and observing the effect on the DNA and RNA levels in the liver. Whilst the former was unaffected, the latter dipped¹⁹. Boivin took up Davidson's idea and in 1948 a group in Paris presented more striking results which they claimed justified the following conclusions:

"... the absolute quantity of desoxyribonucleic acid enclosed in each nucleus maintains an unchanging value in the course of the most severe fast ...

The invariability of DNA appears as a natural consequence of the special function which is now attributed to it, that of being the depository of the hereditary characters of the species. As for the variability of the RNA; this is easily explained by the very active role which one is inclined to give it in the process of cellular synthesis" (Brachet and Caspersson)²⁰.

At a time when isotopic studies were revealing the very rapid turnover of metabolites here was DNA maintaining a much slower turnover. When Mirsky and Ris confirmed the Boivin-Vendrelly rule they also showed how very variable were the quantities of their 'residual protein'—8.5% to 29% of the chromosomal mass, whereas DNA only varied between 26% and 39%. Now it became clear that the earlier reports of wide fluctuations in DNA percentage content were artefacts. They reflected changes in the absolute quantities of chromosomal proteins. Of these, histones were the predominant class, and recent work had shown that their composition in different tissues of the same organism varied immensely, the arginine from 19% in red blood corpuscles to 87% in mature sperm. Mazia pointed out that in the sperm cell of fish the histone type protein has deteriorated into a much simpler protamine type.

"The sperm cell has no function other than to serve as a genetic bridge between two generations; its physiological capacities are limited to activities that will facilitate the transmission of a nucleus into the egg. If the basic protein fraction actually degenerates in the one case

where we can prove that a full genetic complement is transmitted by the nucleus, it is not tempting to think of this fraction as embodying the properties of genes"²¹.

As far as the apparent metabolic inactivity of DNA was concerned, Mazia saw this as agreeing with the 'template' conception of the gene. "The logical implication is that the gene need not 'do' anything but that it merely provides a blueprint for syntheses". In conclusion, he named DNA as the most likely candidate for the role of genetic material.

Mazia was not the only cell chemist to be impressed by the work of Avery, Boivin and Vendrelly. Arthur Pollister at Columbia University, Hewson Swift at Chicago and Max Alfert at Berkeley were all stimulated by these pioneers to establish further parallels between the genes and DNA, and when a discussion meeting was held at Oak Ridge in 1950 on current problems in the biochemistry of nucleic acids, Pollister spoke warmly of Boivin and described the work of the Vendrellys. Nor was Sir Cyril Hinshelwood, the student of bacterial metabolism, unaware of the Boivin-Vendrelly rule, and from his laboratory of physical chemistry in Oxford came evidence for the constancy of the DNA content and the variability of the RNA content of bacterial cells grown under a wide range of conditions. After suggesting a nucleic acid code for amino acid sequencing (but not a one-way code) Caldwell and he concluded:

"The relative stability of the desoxy-component, and its constancy per cell, perhaps reflect its biological function, in so far as it is believed to be the principal seat of the unchanging hereditary characters, in contrast with the more changeable ribose nucleic acid component. This appears in part to be responsible for the bulk of the protein synthesis, and will presumably be the seat of the variable and adaptable characters"²².

Like Boivin, Erwin Chargaff, at the College of Physicians and Surgeons, New York, was impressed by Avery's work and decided to look for chemical differences in the base composition of DNAs from different sources. In so doing he overthrew the tetranucleotide hypothesis and provided Watson and Crick with the most significant clue to their model—the 1:1 base ratios. It is noteworthy that this achievement was only made possible by the development of chromatography. Just as nucleic acid research benefited from new techniques of molecular weight determination after they had been first applied to the proteins, so it now benefited from the introduction into protein chemistry of paper chromatography. Working under Chargaff, the Swiss chemist, Ernst Vischer, adapted the technique to nucleic acid decomposition products. Fortunately they worked on strikingly different DNA types—the tubercle bacillus (with high content of guanine and cytosine) and yeast DNA (with high content of adenine and thymine). Despite this contrast there was a remarkable approach to equality in the ratios A/T and G/C as in Table 2. In 1950 *Experientia* carried Chargaff's paper on "Chemical Specificity of Nucleic Acids. . ." In his conclusion he affirmed the existence of "an enormous number of structurally different nucleic acids: a number, certainly much larger than the analytical methods available to us at present can reveal"²³. He went on to calculate the number of possible sequences exhibiting the same base proportions as those of the ox. For a chain of 100 nucleotides it was

TABLE 2 Base ratios obtained by Vischer, Zamenhof and Chargaff in 1949

DNA source	Adenine	Thymine	Guanine	Cytosine
Calf thymus	1.7	1.6	1.2	1.0
Beef spleen	1.6	1.5	1.3	1.0
Yeast	1.8	1.9	1.0	1.0
Tubercle bacillus	1.1	1.0	2.6	2.4

10^{50} , for 2500 the number was 10^{1500} . When he addressed a symposium on cytochemistry in 1950 he started by referring to Schrödinger's concept of the hereditary codescript and he went on to give evidence in support of the association of DNA with it. He drew attention to the extension of Avery's work to *E. coli* and *Haemophilus influenzae*. He described his own results, including the classification of DNA into AT and GC types. These facts show that Avery's work did provide the direct stimulus for the most important development in the chemistry of the nucleic acids of that time. No one could claim that Chargaff failed to emphasize the importance of his work, but he failed to achieve a structural explanation of the base ratios.

DNA comes out on top

By the time Watson and Crick came to study the structure of DNA a revolution in the biochemistry of nucleic acids had swept away the old idea of a nucleic acid cycle; a new technique in analytical chemistry had broken the back of the tetranucleotide hypothesis; and from physical chemistry had come new techniques which spelt out the polymeric nature of DNA. By 1950 the chemical and biological specificity of DNA was emerging. To be sure there were qualifications and doubts, halfway positions—the gene is DNA and protein—and just sheer ignorance of these developments. They took several years to spread, and would have taken longer had not the Watson—Crick model speeded up the process. In the meantime one had to read the right literature or belong to the right magic circle. Watson and Crick, by their own admission, did not at first read the literature of nucleic acid chemistry. Most of their clues came from the Phage Group, which until 1952 was ambivalent over DNA and protein. On the other hand members of the Phage Group were not bothered with chromosin or chromosomin; they knew that the nucleic acid of the phage entered the host cell, and by 1952 they were very doubtful that any protein did. On the other hand they were rather arrogant about chemists, so it was not from the Phage Group that Watson and Crick learned about the base ratios, but from Chargaff

himself, when they met him in Cambridge in 1952. Some nine months after that meeting they published their famous model in *Nature*. The key to the model was the pairing of the bases, and this was done in accordance with the Chargaff rules—adenine with thymine and guanine with cytosine, so that $A/T = G/C = 1$. Now, 21 years later, what a rich harvest has been reaped from that neat idea!

New directions in molecular biology

Sydney Brenner

MRC Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 2QH, UK

"Much has been written about the philosophical consequences of molecular biology. I think it is now clear what the entire enterprise is about. We are looking at a rather special part of the physical universe which contains special mechanisms none of which conflict at all with the laws of physics."

MOLECULAR biology is nothing more than the search for explanations of the behaviour of living things in terms of the molecules that compose them. It is therefore quite an old subject, older than the discovery of the structure of DNA which Watson and Crick announced in this journal 21 years ago. Biochemistry existed as a major scientific enterprise for many years before 1953 and it had made considerable advances in our understanding of intermediary metabolism and biosynthesis in molecular terms. When the double helix appeared it made very little immediate impact on the biochemical establishment which was largely preoccupied with questions about the transformation of matter and energy in

biological systems. It was also viewed with suspicion by most biologists who felt that the complex phenomena of heredity and development could not possibly be explained by what appeared to them to be an excessively simplistic theory. The strong response to the discovery came from quite a small group who took up the new ideas with great fervour. My memory of the early days is that of a small and rather select evangelical movement which often experienced great difficulties in convincing the disbelieving heathen. Looking back, one can now see that the double helix brought the realisation that information in biological systems could be studied much in the same way as energy and matter. It turned genes into chemical objects whose structure and function could be analysed and understood in terms of biochemical machinery.

How this programme, which was only implicit in 1953, has come to be practically realised is now a matter of history. Everybody knows that it depended on the development of powerful methods for fractionating and detecting large molecules, on advances in physical instrumentation and on the judicious choice of organisms for research and their ingenious

genetic manipulation. There were also two other factors which conditioned the explosive growth of the subject and which are not generally emphasised. The double helix fundamentally changed the image of biology. To most young people of my generation the biology taught in universities was a most unattractive subject. It seemed to consist in learning long dusty lists of Latin names punctuated by cutting up frogs or carrots in long dusty laboratories. DNA changed all of that and turned biology into an exciting, intellectually attractive, subject. As a result, large numbers of extremely talented and clever young men who might otherwise have become physicists were drawn to it and the edifice of molecular biology that we have today owes much to their ingenuity and hard work. The second factor was simply the massive expansion of governmental financial support for science and higher education, particularly in the United States, which provided the material base for the rapid growth of molecular biology. Watson and Crick may have invented it but Uncle Sam certainly fuelled it.

Communication

So much for the past; this article is supposed to be concerned with the future. To try to pick out new directions in molecular biology and to do it in a way acceptable to most people has proved to be an impossible task. One of the consequences of the growth of the subject is the vast literature it has generated which nobody can read in its entirety. I estimate that the leading journals alone produce about 10^5 pages of material per year which, in all scholarly conscience, ought to be studied. Nobody can do this and most molecular biologists tend to be conversant with only a small part of the field and rely on others telling them what is interesting or new elsewhere. The rumour, propagated by word of mouth or telephone, has become the main vehicle of communication. If you want to keep something secret in molecular biology, you publish it but do not talk about it. New directions and new ideas in the subject are often generated by one or a small number of people but they become rapidly communalised by this anonymous process of verbal transmission. Here they are held in a reverberating form until someone does the crucial experiment. When that happens, growth can be explosive; if nothing happens, the idea simply peters out. It is this concentration on the experiment that gives molecular biology its rather distinctive and ruthless character and it probably explains why (with the possible exception of Francis Crick) there are no living theoretical biologists. To write about new trends in molecular biology is to tackle a very tenuous field and I can only do it in a very general way.

Developmental biology

First it is clear that the new parts of molecular biology are just the old parts of biology. There has been an increasingly popular move from the study of prokaryotic microorganisms to work on multicellular eukaryotes. Those problems of higher organisms that are directly amenable to the methods of molecular biology have fallen rapidly beneath the axe; antibodies and hormone and drug receptors are recent examples and the analysis of intracellular organelles such as mitochondria is another noteworthy instance. The problem that has only barely been dented is that of development. It is a very old problem indeed. At the turn of the century Thomas Hunt Morgan left embryology to enter the new field of genetics in the hope that it might cast light on the intractable problems of development. One view of modern molecular biology is that it has completed Morgan's deviation and we are now back with the same unsolved problems. How do the genes specify the complex cellular structures that we find in higher organisms? What controls the temporal sequence of development, the geographical layout of cells and their connections, and specific biochemical differentiation? It is not good enough to answer these questions by saying it is simply a matter of turning some genes on and others

off at the right times. It is true that molecular biology provides numerous detailed precedents for mechanisms by which this can, in principle, be done, but we demand something more than these absolutely true, absolutely vacuous statements.

It is interesting to ask whether the problems of developmental biology could be solved by one insight as penetrating as that of the double helix. This is really asking whether higher organisms have some unique piece of molecular biology that is unknown to us. There is a strong tendency of molecular biologists to use every new molecular device uncovered as a basis for a new theory of development. Antibody molecules are composed of heavy and light polypeptide chains which are themselves specified by stitching together a variable and a common gene sequence. There have been numerous speculations on applying this mechanism to the generation of molecular diversity in developing systems. My impression is that these ideas exist in a kind of limbo, neither accepted nor rejected, and probably not even generally discussed. The attitude is that there is nothing to talk about until someone either proves that this is a more general mechanism and not something specific to the immune system.

The general belief is that developmental biology will not be solved at one stroke but its problems will be partitioned into subproblems each of which could be tackled separately, preferably in a model system. One example is cell movement and growth. Clearly, how cells move in relation to each other and how they send out processes is central to understanding development. It is now well established that the motility in cells is generated by actin and myosin molecules closely related in structure to their counterparts in muscle. This turns out to be true of amoebae as well so that the same phenomena with the same underlying molecular mechanism can be studied in detail in a simpler experimental system. It is likely that many more analogous cases will be found and that the cytoplasmic mechanisms of higher cells which provide the machinery of development will, one by one, be isolated and studied in this way.

Eukaryote chromosome structure

There are two problems which are at a different stage of study and which are of great interest at the present moment. The first is the structure of the chromosomes of eukaryotes; the second, the cell surface. It is by now well known that the DNA of higher organisms presents a strange paradox. In brief, there seems to be too much of it for what we think it ought to be doing. When genetic results are compared with the unique sequence content of the DNA in different organisms, the genetic units turn out to be very large. In *Drosophila*, an average gene contains about 20,000 base pairs which is much larger than the 1,000 base pairs required to code for the average polypeptide chain. This is over and above the problem posed by the presence of an even larger excess of redundant sequences. The chromosomes of higher organisms also differ from those of prokaryotes by their content of specific proteins like histones and their far more complex structure. Many theories have been proposed to explain these observations, in terms of the special structural or control requirements of the cells of higher organisms. Solving the structure of chromatin is a very active field at the present moment and success is likely to throw much light on these problems.

An interesting consequence of this new work is that the number of genes in higher organisms is much smaller than we might have been led to expect from their DNA composition. It suggests that *Drosophila* might have as few as 5,000 genes and the small nematode *C. elegans* perhaps only half that number. Using various methods of maintaining lethals it should be possible to isolate mutants in every gene in such organisms. For each of these mutants, as has already been done in a few instances, one could look at the developmental consequences and, with temperature-sensitive alleles, one

could determine the time of action of the gene. Could we gain a detailed understanding of development from this approach? One view is that this might allow us to deduce the logical structure of the genetic programme by seeing whether there are partitioned subsets of genes which correspond in some interesting way to the phenotype. Questions of this sort are not strictly molecular being concerned more with the software of organisms than with their hardware. In the long run, however, we must find the molecular implementations. This would involve identifying the products of the genes and finding out which cells have them and where and when they work to produce their effects. But to do this requires high resolution protein spectroscopy and this technology only exists in a crude and cumbersome form today. Not many people would be willing to embark on such a programme because of its intrinsic magnitude, and there are also many workers who would object on grounds of principle to this approach. There is in fact a fairly large antigenetic school of molecular biologists who believe that the work should proceed from the biochemistry and not the other way around. The only difficulty is that, except in special cases, nobody knows what biochemistry ought to be done.

Cell surface

This brings me finally to the question of the cell surface. One of those nebulous communally circulating ideas is that the cell surface contains the key to the mechanisms of development. These notions have been generated from many different sources. Some come by extrapolation from cell interactions in the immune system, others from the develop-

ment or regeneration of neural connections, and yet others from the study of the reaggregation properties of embryonic cells. The central thought is that cells or groups of cells carry a specific chemical code on their surfaces and by this code they know themselves and their neighbours. In the pages of this journal there have appeared various baroque forms of this theory in which gene stitching, reverse transcriptase and other pieces of molecular clockwork have been grafted onto the idea of specific chemical labelling of cells. Nobody will deny that cells do have surface proteins and that some of these will be involved in recognising specific chemical signals such as nerve transmitters or hormones. The real question is whether there really exists a system which, by one mechanism or another, can generate 10^6 chemical names and plant these on the right cells. There seems to be no convincing general argument either for or against this view and only time will tell.

Much has been written about the philosophical consequences of molecular biology. I think it is now quite clear what the enterprise is about. We are looking at a rather special part of the physical universe which contains special mechanisms none of which conflict at all with the laws of physics. That there would be new laws of Nature to be found in biological systems was a misjudged view and that hope or fear has just vanished. Our job is simply to find out how these interesting pieces of machinery work, how they get built and how they came to be the way they are. In one sense, the answers already exist and all we have to do is to find out how to look them up in Nature. That is why molecular biology seems to me to be the art of the inevitable.

Rosalind Franklin and the double helix

A. Klug

MRC Laboratory of Molecular Biology, Cambridge, UK

A draft manuscript shows how near Rosalind Franklin came to finding the correct structure of DNA.

SOME years ago I gave an account¹ of Rosalind Franklin's contribution to the discovery of the structure of DNA, based on published sources supplemented by references to her notebooks and reports. I pointed out how close Franklin had come in the progress of her work to various features of the structure contained in the correct solution. At the time, however, I did not know of the existence of a draft manuscript which confirms how close she had got to the answer. This only came to light later. I therefore take the opportunity of this 21st Anniversary issue to fill out the record and to highlight a dramatic element in the 'race' for DNA.

In my article I told how the analysis of the B form of DNA in terms of helical diffraction theory, which is given in Franklin's paper with Gosling in *Nature*² on April 25, 1953, can be found in her notebook for the period January to March 1953, that is before the Watson-Crick structure had become known to her. I went on to say, however, that she apparently did not feel convinced enough of the relevance of this analysis to publish it (because she had not solved the A form). This is erroneous. The typescript I have found is dated March 17, 1953 and is clearly a draft of the *Nature* paper. This suggests a different explanation from the one I gave, namely that she was proposing to publish what she knew on the B form, two other papers on the A form having already been submitted (before March 6) to *Acta Crystallographica*. This draft contains all the essentials of the *Nature* paper, and much of the wording is carried over intact. It required only slight modifications to take into account the Watson-Crick structure, news of which reached

King's College on March 18, one day later.⁴ In the final (undated) typescript, there is inserted by hand the sentence "Thus our general ideas are not inconsistent with the model proposed by Watson and Crick in the preceding communication."

In the draft it is deduced that the phosphate groups lie on a helix of diameter 20 Å, that is, on the outside of the molecule, in accordance with the conclusion Franklin had reached earlier on the basis of physicochemical reasoning, including her own work on the water uptake by DNA fibres undergoing the A-B transition. Moreover, on the basis of the intensity distribution in the X-ray pattern, she concludes that there is not one chain in the helix, but probably two, coaxially arranged, and that these are separated by $\frac{3}{8}$ of the period, or 13 Å, along the fibre axis direction. The wording is so couched, however, as to show Franklin had not yet understood that the two chains must run in opposite directions, although she had already observed in her notebook that this must be the case in the crystalline A form (which has a two-fold axis of symmetry). I have already argued that it would not have taken long for her to see the true relationship between the two forms—at the time she was thinking of the A form as an unwound version of the helices in the B state (rather, I imagine, like the β -sheet structure is to the α helix in polypeptides).

This would have brought her to the final and crucial step necessary to the complete solution, base pairing. Franklin had thought from an early stage that the bases must lie on the inside of the molecule and be linked by hydrogen bonds, and she had already formed the notion that the two purines were interchangeable with each other and also the two pyrimidines³. An entry in her notebook shows that she was considering Chargaff's analytical data, though there is nothing

to show that she knew the correct tautomeric forms of the bases. The step from base interchangeability to base pairing is a large one, but the idea would have been essential to fitting the variable parts of the structure, the bases, in, to the regularly repeating part, the double helix of phosphate-sugar chains at which she had arrived by March 1953.

Molecular biologists come of age in Aries

Donald A. Windsor

Post Office Box 604, Norwich, New York 13815

It seems that more molecular biologists are born under Aries than any other sign.

ONE major tenet of astrology is that the 'Sun sign' (the constellation of the zodiac in which the Sun was located at the moment of a person's birth) has a powerful influence on

personality¹. I have compared the birthdays of two very different kinds of biologists—taxonomists and molecular biologists. All names listed under all of the taxonomy terms (cyto-, insect, and plant taxonomy; systematic botany, entomology, ichthyology, and zoology; systematics; taxonomic botany, and taxonomy) and all of the molecular biology terms (molecular biology, biophysics, genetics, pharmacology)

TABLE 1 Relative frequencies of births under the different Sun signs

Sun sign	Taxonomists			Molecular Biologists			General Population		
	No.	%	Index	No.	%	Index	Month	%	Index
Aries	28	8.2	98.2	58	12.3	148.0	March	8.4	101.4
Taurus	30	8.8	105.3	32	6.8	81.6	April	8.1	97.1
Gemini	31	9.1	108.8	39	8.3	99.5	May	8.1	97.5
Cancer	38	11.1	133.3	41	8.7	104.6	June	8.2	98.9
Leo	32	9.4	112.3	32	6.8	81.6	July	8.6	103.7
Virgo	31	9.1	108.8	42	8.9	107.1	Aug	8.7	104.8
Libra	25	7.3	87.7	41	8.7	104.6	Sept	8.8	105.4
Scorpio	18	5.3	63.2	41	8.7	104.6	Oct	8.2	98.4
Sagittarius	27	7.9	94.7	40	8.5	102.0	Nov	8.0	95.6
Capricorn	25	7.3	87.7	33	7.0	84.2	Dec	7.9	94.6
Aquarius	26	7.6	91.2	35	7.4	89.3	Jan	8.3	100.0
Pisces	31	9.1	108.8	36	7.7	91.8	Feb	8.6	102.7

FIG. 1 Relative frequencies of births, expressed as index values, under the different Sun signs for taxonomists (---) and molecular biologists (—); also shown are monthly birth data for the United States in 1934 (....).

were taken from the Discipline Index² of the twelfth edition of *American Men and Women of Science*³. The birthdays were obtained from the main reference portion and the appropriate sun signs were assigned. Names appearing more than once were only counted once. A great deal of variation occurs in the dates for these signs because the sun does not always change signs at midnight, so I used the dates given by Goodman¹. Not all scientists listed had birthdays given. The numbers of persons born under each sign were tallied and the relative frequencies were expressed as an index (each value divided by the average, times 100)⁴ (Table 1, Fig. 1). The monthly birth data for the general population of the United States for 1934 are given for comparison; this is the year closest to the births of most of the scientists now recorded, for which good data are available.

More molecular biologists were born under the sign of Aries than any other sign. More taxonomists were born under the sign of Cancer than any other sign and relatively few were born under Scorpio. Since these peaks do not coincide with the peaks for the general population and are sometimes contrary to them, they are even more remarkable.

(Continued from page 764)

FIG. 2 Separation of iodinated rat erythrocyte polypeptides. Erythrocytes were isolated and iodinated as described in the text. Labelled cells were injected into animals and blood samples were collected at various times thereafter. Erythrocytes were washed free of serum proteins, and the plasma membranes were isolated. Membranes were then solubilised in 2-3% SDS and separated by electrophoresis on 5% polyacrylamide gels containing 0.1% SDS⁶. The distribution of radioactivity in the gels was determined by slicing the gels into 2 mm slices and then determining the radioactivity in each slice. The profiles shown are from erythrocyte membranes isolated from animals 1 h (a); 19 h (b); and 404 h (c), after injecting labelled cells.

components of larger molecular weight are degraded^{5,6} more rapidly. In the erythrocyte membrane this apparently is not the case; all components seem to have approximately the same half-life which is significantly shorter than the half-life of the whole cell.

There may be several reasons for the short half-life of membrane components observed with the iodine probe. One possible reason is that the labelled components are de-iodinated. There is a report of de-iodination activity in the erythrocyte membrane¹⁶. It is also possible that the proteolytic activity^{17,18} present in the red cell may account for the removal or loss of label due to proteolysis of the membrane component.

The most probable explanation for the short half-life observed with the iodine labelling is based on the observation that young erythrocytes are larger than old ones. The decrease in cell size is probably due to sloughing off of the membrane (see, for example, ref. 19) within the sinusoids of the spleen and liver. This process takes with it relatively small quantities of the internal components of the red cell, but probably relatively significant quantities of membranes with much smaller losses of the internal components of the red cell. Thus, by this mechanism, iodine would not be eluted in the same manner as chromium is presumed to be eluted, but would represent loss of membrane from the cell during the course of its life. Thus, membrane labelling may have advantages in the study of membrane diseases and the survival of the membrane in contrast to the interior of the cell. This method may provide information about the activity or

functional capacity of the spleen and hepatic sinusoid cells in diseases where it is possible that these organs and not the erythrocytes are defective.

Novel human serum protein from fibroblast plasma membrane

CELL surface components play a major role in the control of normal cell interactions and in the altered growth control and antigenic properties of malignant cells¹. To characterise tissue-specific cell surface proteins we undertook an immunochemical study of the material released from cells by mild proteolytic treatment. Our studies have disclosed a fibroblast-specific cell surface and serum antigen in chicken². The amount of this antigen is greatly reduced in chicken fibroblasts transformed by Rous sarcoma virus.

These studies prompted us to search for an analogous protein in humans in light of its possible significance in human malignancies. We describe here a new cell surface protein of human fibroblasts which is also present in human serum, and seems to be the human counterpart of the chicken fibroblast surface antigen.

Antisera were raised against material prepared from the surface of human secondary fibroblasts with insoluble papain² (Enzite-EMA, Miles-Yeda). The antiserum prepared against the papain-released material from fibroblasts, gave a single precipitation line against the immunogen and similar material from four continuous fibroblasts lines: WI-38 (ref. 3), MRC-5 (ref. 4), IHM (human embryonic fibroblast) and 377HEL (human embryonic fibroblast). An antigen in-

Fig. 1 Immunodiffusion in agarose. A and D, Normal human serum; B, papain digest from MRC-5 cells; C, MRC-5 cells extracted with 8 M urea and 1% Triton X-100. Centre well, rabbit antiserum prepared against papain digest from human fibroblasts.

distinguishable from the fibroblast antigen in immunodiffusion and absorption experiments was present in human serum (Fig. 1). The antigen could be solubilised from fibroblasts by papain, trypsin, or by treatment with a solution containing 8 M Urea, 1% Triton X-100, 5×10^{-5} M phenylmethylsulphonyl fluoride and 0.02% sodium azide. Incubation of the cells in buffered saline or EDTA in conditions comparable to the enzyme treatment did not yield detectable amounts of the antigen. Small quantities could, however, be detected in the maintenance medium of fibroblast cultures after 24 h incubation. The antigen was not detected in material released by papain or urea-Triton X-100 prepared from several non-fibroblast human cell lines. The cell lines included U and WISH transformed amnion lines, primary

Fig. 2 Immunodiffusion in agarose (a) followed by autoradiography (b). A, C and E, Normal human serum; B, D and F, foetal extract. Centre well, rabbit antiserum prepared against papain digest from human fibroblast and anti- α -foetoprotein serum. Papain digest from H^3 -fucose labelled MRC-5 cells was added to the peripheral wells, undiluted (A and B) diluted 1:4 (C and D) and 1:16 (E and F). The highest amount of H^3 -fucose labelled digest, in well B, gives a precipitate without carrier antigen from normal human serum. Smaller concentrations in wells C and E coprecipitate with the line between normal human serum and antiserum, while the unrelated control precipitate (alpha-foetoprotein) from wells D and F remains non-radioactive.

normal amnion, HeLa cervical carcinoma, KB (nasopharyngeal carcinoma), Hep-2 (laryngeal carcinoma), P3HR-1 (Burkitt's lymphoma). Material released by papain from washed red blood cells and buffy coat leukocytes was also negative.

That the antigen is synthesised by the fibroblasts and not absorbed from serum was shown by its presence in the established human fibroblast lines grown for over 30 passages in the presence of calf serum which does not contain the human antigen. Cells grown in the presence of 35 S-methionine incorporated radioactivity to the antigen as shown by autoradiography of immunodiffusion precipitates. Similarly, radioactivity was incorporated into the antigen from 14 C-fucose (Fig. 2). Iodination (125 I) using the peroxidase method⁵ labelled the antigen as demonstrated by coprecipitation of radioactivity into a specific immunoprecipitate.

Assay of the antigen after solubilisation of cells in urea and Triton X-100 showed that treatment with trypsin (0.25%, 15 min), such as used in the subcultivation of fibroblasts, removed more than 90% of the antigen from cells without any detectable cell destruction. The antigen was fully restored within 24 h after such treatment. Absorption of the antiserum with living fibroblasts abolished its precipitating capacity in immunodiffusion. These data show that the antigen is an integral membrane glycoprotein and is exposed on the cell surface. No immunological cross reactions were demonstrable between the human and chicken² antigens. Antisera against the human material did not react with extracts from chicken cells or *vice versa*.

We have determined some properties of this protein for which we propose the name soluble fibroblast antigen (SF antigen). In sedimentation analysis we used 5–20% sucrose gradients and human IgM (19S), IgG (7.1S), albumin (4.3S), ovalbumin (3.6S) and pancreatic RNase (1.9S) as reference markers. The S values were calculated according to Martin and Ames⁶. The serum SF antigen sedimented during ultracentrifugation in the 13.5S region. In agreement with the relatively high molecular weight suggested by the S value, the serum SF antigen was precipitated by 25% saturated ammonium sulphate. On immunoelectrophoresis, the serum SF antigen gave a precipitate in the α_2 -region (Fig. 3). The presence of sialic acid in the antigen was indicated by an altered electrophoretic mobility after neuraminidase (Behringwerke) treatment of partially purified serum antigen (Fig. 4). Pronase (Calbiochem, 537088) treatment of partially purified SF antigen destroyed its antigenic activity. For inactivation by Pronase it was necessary to use slightly larger amounts than those required to abolish antigenic reactivity of human serum albumin. Human blood group A substance, used as another control, was not affected by the treatment. These data indicate that the polypeptide chain is involved in the antigenic activity.

The serum SF antigen could be demonstrated in all 60 normal human sera studied and also in smaller quantities in 2 foetal sera. We are now investigating the quantity and possible compositional deviation of the serum SF antigen in various forms of connective tissue disease and in malignancies. The absolute concentration of SF antigen in serum or cells cannot be given at present, because attempts to purify the serum SF antigen in immunoreactive form have so far been hampered by its insolubility after purification procedures. This is in line with the postulated membrane origin of the serum SF antigen, as membrane proteins tend to be hydrophobic. The antigen, however, was detectable in immunodiffusion (sensitivity about $10 \mu\text{g ml}^{-1}$)⁷, in normal human serum diluted 1:10 and in fibroblast samples containing 2.0 mg ml^{-1} of total cell protein. This result indicates that the serum concentration of SF antigen is about $100 \mu\text{g ml}^{-1}$ and it may comprise as much as 0.5% of the total cell protein, which would make it a major component of the plasma membrane.

Fig. 3 Immunoelectrophoresis in agarose. Normal human serum (NHS) tested against anti-normal human serum (A-NHS) and an antiserum prepared against papain digest from fibroblasts (A-SF). Anode to the right.

The SF antigen seems to be the first well defined example of a new type of serum protein, which originates from the cell surface. Other cell surface components, also seem to exfoliate from the cell membrane and appear in circulation, albeit at minute concentrations⁸⁻¹⁰. That the SF antigen is present in serum at high concentrations may be because of the abundance of fibroblasts in the body.

Our recent data (P. Kuusela, E. R., and A. V., unpublished) indicate that the polypeptide composition of the SF antigen in serum and in fibroblasts is very similar, consisting of two major polypeptide chains with molecular weights of about 210,000 and 145,000. This is true of human as well as chicken SF antigens. This shows that the similarity of the cellular and serum antigens is not restricted to a limited antigenic determinant, but is based on a molecular similarity if not identity. This, and the fact that cultured fibroblasts shed the antigens to growth medium, strongly supports the notion that the serum antigen originates from the fibroblast surface.

As a well defined glycoprotein SF antigen may offer a unique possibility to look into the biological significance of circulating cell surface components, it has been suggested that growth regulation¹¹ and the maintenance of immunological tolerance¹² could be mediated by such molecules.

It is predictable that cell-type specific surface glycoproteins, such as SF antigen, may be important for the interactions between normal cells and perhaps function as recognition molecules¹³⁻¹⁶. Our observation that reduced amounts of the chicken SF protein², analogous to the human protein described here, are present in virus transformed cells¹⁷, is in line with this proposal. Our recent data (A. V., and E. R.,

Fig. 4 Immunoelectrophoresis in agarose. Effect of neuraminidase on the electrophoretic mobility of partially purified SF antigen. A, Neuraminidase treated; B, control treated (without neuraminidase) SF antigen tested against A-SF serum.

unpublished) indicate that human fibroblasts also lose their SF antigen after transformation. This indicates that the biological role and the possible diagnostic significance of the human SF antigen and related cell surface components in human malignancies deserve further attention.

Composition drift in the cytochrome c cistron

In a previous letter I showed that the distribution of base frequencies for degenerate codon positions is far from random in the only completely sequenced mRNA, the coat cistron of MS2 coliphage¹. The study reported here indicates a strong evolutionary trend among non-degenerate bases in mRNA for the cytochrome c series leading to man.

Forty-three best resolved cytochrome protein sequences have been decoded to obtain theoretical mRNA base compositions, assuming equal use within the set of codons of each amino acid¹. The adenine content in each theoretical mRNA is correlated with the estimated palaeontological age for that type of organism (Table 1). Although fewer fish and insect sequences are available, each age is fairly well represented. Many cytochrome c molecules from plants have been sequenced but only one, ginkgo, which is believed to be the most primitive² and thus the closest to the line leading to man, is included to avoid weighting plants too heavily in the correlation. Simply decoding every cytochrome c ever sequenced, however, while making a bulkier analysis, would not greatly affect the trends shown.

TABLE 1 Adenine content in cytochrome mRNA

(a) Palaeontological age and adenine content of theoretical mRNA

(b) Correlation between age and %A in theoretical mRNA									
No. organisms	Span: from man to	-r*	-b*	a*					
24	Insects	0.89	6.5	37.1					
32	First eukaryotes	0.82	3.3	36.2					
43	All bacteria + alga	0.77	2.0	35.6					
36	<i>Pseudomonas</i> c551 only	0.91	3.0	36.1					

* r is linear regression correlation coefficient, b is slope (%A per 10^9 yr), a is intercept at time zero (present).

I have tried to take a least controversial figure for each evolutionary age. Ages of bacteria and algae are generally estimated at around 3×10^9 yr^{3,4}, first eukaryotes at 1.2×10^9 to 1.8×10^9 yr^{5,6} and insects at 600–1,000 Myr^{4,7,8}; agreement is better on dates for more recent organisms (from lamprey onwards). The conclusions of this paper would not change if some of the ages in Table 1 are wrong by 25%–30%.

The adenine content in cytochrome *c* theoretical mRNA has increased by about 5% (absolute) since the appearance of eukaryotes. This is an enormous value in a cistron which already contained a considerable amount of A (29%–33%) at that time and which evolves slowly. Just when the trend started is uncertain, however, because the ancestry of cytochrome *c* in bacteria and algae is not clear^{4,6,9-11,12}. The trend may be accelerating, as a comparison of the magnitudes of the three slopes suggests (human–insect > human–first eukaryotes > human–bacteria and alga, see Table 1b). But perhaps insect divergence goes back almost to the appearance of eukaryotes.

A bacterial or algal ancestor cistron containing 35%–37% A is unlikely because of the lower percentage of A for intermediate organisms (protozoa, insects and fish) accepted as having cytochrome *c* homologous with that of man. Also, all fifteen theoretical mRNAs from bullfrog onwards, on the evolutionary scale, have at least 35% A whereas none of the eleven bacterial and algal ones have as much as 35%. In fact, judging composition trends, *Pseudomonas* c551 is a more likely candidate for the ancestor of mammalian cytochrome *c* than is *Rh. rubrum* c2. Mammalian cytochrome *c* has 72% (relative) more Lys and 38% more of the combined five amino acids besides Lys with a high percentage of A in their codons (Asn, Gln, Glu, Ile, Thr) than has *Pseudomonas* c551. Lysine codons have an average A content of 83.3% whereas codons from the other five amino acids average 50% A. As a generalisation, evolutionary change of each residue in cytochrome *c* is proportional to the adenine content of its codons. This cannot be explained by increasing polarity because two (Ile, Thr) of the five amino acids have low polarities. Furthermore, highly polar Asp (whose codons have an average of 33.3% A) has decreased in frequency while less polar Asn¹³ (whose codons have an average of 66.7% A) has increased during this interval. The evolu-

tionary progression of the six amino acids with codons of high A content is summarised in Table 2.

Neither a classical selectionist nor a neutralist interpretation of these findings seems possible. Unless a bias in the choice of organisms to sequence somehow exists, however, there is no escaping the fact of a general, progressive increase of all codons of high A content in the cytochrome *c* line. There are two conceivable models for the trend. In the first, cistron evolution proceeds by a general increase of codons containing a predominance of adenine while no special control is exerted on degenerate bases. Alternatively, the observed increase in non-degenerate A is compensated by appropriate choices among degenerate bases to contain the drift in total cistron composition¹.

mRNA sequences will help to decide between these models. The actual mRNA in cytochrome *c* will have had to gain considerably in A content unless numerous silent mutations (ones not affecting amino acids) have occurred. This is readily seen by aligning, for example, horse and silkworm moth cytochrome *c* sequences. Ignoring non-homologous ends (last horse and first four moth residues) and noting possible base changes in codons of exchanging amino acids, the adenine content of horse mRNA can be lowered at most by 1% by avoiding A as a degenerate base in replacing codons, whereas the theoretical adenine difference between the two species is 5%.

Other proteins show trends in the choice of non-degenerate

TABLE 2 Evolutionary progression of amino acids with codons of high adenine content

No. of sequences	Type	Average in cytochrome % Lys	% NQEIT*
11	All bacteria and alga ^{4,11,14-17}	13.0	19.4
(1)	<i>Rhodospirillum rubrum</i> c2 ⁴	15.2	24.0

8	Mammals + kangaroo ^{4,24}	17.4	29.2

* Asn + Gln + Glu + Ile + Thr.

codon bases (for example, the theoretical mRNA in haemoglobin α chain has increased sharply in C content during its evolutionary life) but fewer sequences or confirmed compositions are available for each series.

It seems, therefore at least for composition trends, that gene evolution is not following a random course. This seems a genuine case of long-term oriented molecular evolution. Whether or not archaic morphology means archaic genes, the correlation in Table 1 remains to be explained. The question is how independent are genetic and phenotypic evolution (further work in preparation).

I thank C. Gautier and J. M. Legay for their help.

Fusion of fungal protoplasts

RESEARCH on fusion of cells of higher eukaryotes is in an advanced stage and excellent reviews have been published concerning fusion of both animal cells¹⁻⁴ and plant protoplasts⁵⁻⁷. On the other hand, no information is available regarding the results of fusion of fungal protoplasts, in spite of its possibilities for basic and applied research. Here we present evidence that fungal protoplast fusion and heterokaryon formation can be achieved. In our experiments no stimulants of protoplast fusion were employed. In fact, a fungus was used in which we have never observed anastomosis and heterokaryosis or sexual processes.

Nutritionally deficient stable mutants were produced from *Geotrichum candidum* SzMC 0055 with N-methyl-N'-nitro-N-nitrosoguanidine ($50 \mu\text{g ml}^{-1}$, 60 min, 10^4 arthrospores ml^{-1}). Auxotrophic mutants requiring adenine (*ad*), lysine (*lys*), isoleucine, and methionine were used. Nutritional complementation by protoplast fusion could be achieved with any pair of these auxotrophic mutants, but results reported here refer to the *ad* and *lys* mutants.

Protoplasts were formed from rapidly growing hyphae ($100 \text{ mg fresh weight ml}^{-1}$) after 2-mercaptoethanol treatment⁸ by using lyophilised snail digestive juice (1.5%), with 0.6 M KCl or 0.8 M mannitol or glucose as osmotic stabiliser at pH 6.5. Almost complete protoplast formation was attained within 2 h. After enzyme removal, protoplasts (10^8 ml^{-1}) from the two mutants were mixed in a ratio of 1:1 and 10 ml portions in the osmotic stabilisers at pH 5.5 and 7.0 were sedimented in 1 cm diameter centrifuge tubes at 2000g. The sedimented protoplasts were kept at 4 or 20° C for 12 h, resuspended, plated on osmotically stabilised minimal medium containing 2% agar and covered with a thin layer of the same agar medium by spraying. The hot agar solution (approximately 80° C) was sprayed in sterile conditions with the aid of an atomiser from the distance of about 50 cm. The temperature of the agar droplets was about 30° C at the time of reaching the surface of the inoculated plates. Slightly better results could be obtained if the surface of the plates were allowed to dry before spraying. The thickness of the covering layer was about 0.2 mm. By using the spraying method, almost 100% protoplast regeneration could be achieved with the prototrophic *Geotrichum* strain, or with auxotrophic mutants in supplemented media. Plates were incubated at 30° C and checked for nutritional complementation.

With mannitol or glucose as stabiliser, complementation occurred with low but constant frequency. At 20° C the average frequency of complementation was 1.6×10^{-6} per protoplast pair at pH 5.5, and 6×10^{-7} at pH 7. At 4° C the proportion of complemented cells was even lower. Complementation did not result with KCl as osmotic stabiliser.

No colonies appeared from separately treated protoplasts of the auxotrophic mutants; nor if arthrospores or growing hyphae of the two mutants were mixed, kept together, and plated as for protoplasts; nor if mixed but not sedimented protoplasts were plated; nor if protoplasts of one mutant were mixed with burst protoplasts from the other mutant.

Colonies derived from complemented cells differ char-

Fig. 1 Macrocolonies of *Geotrichum candidum*. a, Prototrophic strain on minimal medium; b, Heterokaryon (*ad*+*lys*) on minimal medium; c, *ad* mutant on minimal medium supplemented with $50 \mu\text{g ml}^{-1}$ adenine; d, *lys* mutant on minimal medium supplemented with $50 \mu\text{g ml}^{-1}$ lysine.

acteristically in colour and morphology from the colonies of the original prototrophic strain and those of the parent auxotrophic mutants. The prototrophic strain and the *lys* mutant are white, the *ad* mutant is red; colonies of heterokaryons are different shades of pink. The morphological differences are illustrated in Fig. 1.

Serial transfer of the complemented hyphae could be performed indefinitely using minimal medium. Complementation, however, was temporary. Complemented hyphae transplanted using media rich in adenine and lysine gave rise mainly to auxotrophic arthrospores. In agar cultures, the proportion of segregation into *ad* and *lys* mutants differed from colony to colony. Between the segregants, the *lys/ad* quotient proved always higher than 1, with the highest value of 6.5 and the lowest of 1.4. The average ratio in colonies 2 d old was 6:3:2, *lys*, *ad* and complemented arthrospores respectively. This ratio changed with time, the growing colonies bearing proportionally fewer and fewer complemented arthrospores.

Colonies developed from complemented arthrospores again bore nutritionally deficient arthrospores. Permanently complemented cells have not been observed up to the present.

From complemented hyphae grown on minimal medium, mostly complemented arthrospores were obtained, although arthrospore formation was rare, especially within the liquid. A considerable number of auxotrophic colonies, however, could be regenerated from protoplasts produced from complemented hyphae after repeated protoplast formation.

Nutritionally deficient stable mutants of *Geotrichum candidum* offer many technical advantages in studies of the conditions required for a more efficient means of fungal protoplast fusion. Further studies with *Geotrichum candidum* and other species to increase the frequency of successful fusion are in progress.

It may be mentioned that morphological alterations are not confined to *Geotrichum*; after protoplast fusion of nutritionally deficient *Aspergillus nidulans* mutants, well-defined differences can also be observed between colonies of the wild-type strain and those of the heterokaryons.

Mechanical shocks induce phenocopies of developmental mutants

In the multicellular green alga *Ulva mutabilis* Føyn, the early division pattern and cellular differentiation can be influenced by exposing the zygotes to mechanical shocks created by a sledge-hammer. The treated plants mimic certain mutants with an abnormal division pattern and/or with less cellular differentiation than wild type. Figure 1c, and Fig. 2c, show

examples of two types of abnormal plants induced by two different strokes of the sledge-hammer, and Fig. 1a, Fig. 2a, Fig. 1b, and Fig. 2b, show corresponding stages of the wild type and two developmental mutants.

Normally the wild type starts its development by forming a filament consisting of a row of cells. When the filament is about 16 cells long, the division planes become orientated through the longitudinal axis and the germling is, essentially, transformed into a tube closed at both ends. The proximal part differentiates into a holdfast with large stem cells and elongated rhizoid cells, while the distal part flattens and expands as a sheet consisting of a double layer of polygonal cells.

A number of mutants have been isolated, which instead of the three morphologically distinct cell types of wild type contain only one or two. Some of these mutants pass a filamentous stage¹ but others do not and develop as hollow spheres² or as aggregates of cells³. At least some of these mutations seem to be in genes active during early stages of development^{4,5}.

The direction of the first division plane of wild type can be set by applying unidirectional light or an electrical field for a certain period about 24 h before the first division⁶. The division plane is then perpendicular to the vectorial stimulus and to the surface on which the cells are growing. The following planes are always parallel to the first and cannot be influenced by light or an electrical field. Filamentous growth, however, is not dependent on a vectorial stimulus of any duration, because normal development occurs when zygotes are grown in agitated suspensions. Centrifugal forces up to 280,000g or ultrasonic treatment given before the first division, do not affect development. Morphogenesis is also normal when the amount of light is reduced and growth is extremely slow.

Until now, the only treatment we have found which affects morphogenesis is exposure of the zygotes to mechanical shocks. The idea came from the work of Kamiya and Kuroda⁷, whose 'hammer experiment' succeeded in releasing *Nitella* chloroplasts from their cortical positions.

Zygotes were prepared⁸ and allowed to settle overnight on cover slides 18 × 18 mm. Thereafter, they were exposed to routine culture conditions⁴ with a light: dark cycle (0400h–1700h, light; 1700h–0400h, dark) starting about 9 a.m. The following day the glass, with hundreds or thousands of zygotes, was placed on the honed surface of a sledge-hammer (Fig. 3) and kept there by an O-ring pressed against the glass by a lid fastened with three screws. An anvil was struck with the other end of the hammer. The zygotes were then cultivated further and a clearcut effect could at the earliest be observed when the zygotes started to divide

FIG. 1 a, Wild-type germling; b, two developmental stages of the mutant lumpy; c, two developmental stages of a wild-type zygote exposed to mechanical shocks at an age of 1d (2 d before the first cell division in the controls).

FIG. 2. *a*, Wild-type plant about 4 weeks old (*h*, holdfast); *b*, mutant 4b about 4 weeks old; *c*, wild-type plant about 4 weeks old. The plant was exposed to a mechanical shock as a 1-d-old zygote.

48–72 h later. The possibility that the effect of the stroke is created by a sudden increase in hydrostatic pressure within the O-ring is excluded, because plants outside the ring also react.

Our first experiment showed that all zygotes on a glass developed in the same way. Of 11 successive strokes, four gave normal plants, two gave plants which did not form a proper filament and showed delayed differentiation, and five gave plants which passed a filamentous stage, but did not differentiate a proper holdfast. Numerous other experiments have given similar results, and the two types of abnormal plants have been recorded repeatedly.

The first kind of abnormal development is illustrated in Fig. 1*c*. The division planes are arbitrarily arranged and the plants develop as cellular aggregates similar to those of the mutant *lumpy* (Fig. 1*b*). The walls between the cells appear curved instead of straight. Even before division, there is the impression that something is wrong with wall architecture and at high magnification the outline of the walls seems thicker and more irregular than normal. The generation time of the cells is longer than usual and differentiation is delayed for weeks if not months. The change induced by the stroke should therefore be considered heritable through many cell generations. Finally some cells regain normality and wild type plants sprout from the aggregate.

The second kind of effect is illustrated in Fig. 2*c*. The plants develop as filaments and are transformed into tubes. The proximal differentiation of the large stem cells and the flattening of the distal part does not take place. They re-

produce much earlier than wild type. The effect of the stroke can already be seen on the filaments. In wild type, the width of the cells decreases from base to apex but in the treated plants the cells are more uniform. The development of secondary rhizoids is also delayed compared to the controls, but a fair amount of rhizoid cells will develop and fasten the plant to the substratum. The abnormal plants mimic a certain type of developmental mutants (Fig. 2*b*) not previously described.

In one experiment, zygotes 1, 2, 3 and 4 d old were treated. Ten blows were struck each day, and of them five, four, three and five strokes respectively had an effect on development. There is therefore no indication of a period before the first division, when the zygotes are especially vulnerable. When the head of the sledge-hammer was dropped through an iron pipe onto the anvil from heights of 6, 12 and 18 m, three of eight, nine of eleven and four of eleven experiments gave abnormal development. The experiments were repeated with a steel cylinder, made to accommodate the zygotes in the same manner as the sledge hammer, but numerous trials from the same and even greater heights, gave no effects at all. The cylinder was a little shorter than the sledge hammer, had no hole for a shaft, but was given the same hardness as the hammer. No effects were obtained when the cylinder was fastened to a shaft by a ring-shaped holder and used as a hammer.

Our experiments show clearly that the wild-type zygotes of *Ulva mutabilis* can be induced to mimic the development of certain mutants. It is important to note that either the plants do not react at all to the treatment, or every single plant of the exposed population reacts by following a particular abnormal developmental path. It is also of significance that effects were obtained with a particular sledge hammer, and that the results could not be repeated by using one of another form. These facts raise the question if the different effects are due to different shock waves, created because one stroke is not exactly like another.

It is common opinion that the early development depends on the cytoarchitecture of the cell, especially the cortex, and it is therefore possible that the treatment distorts the cytoarchitecture of the zygotes in an irreversible manner. There is the most interesting possibility of changing the

FIG. 3. The sledge-hammer with which the effects were obtained. *a*, The honed surface on which the cover-slide with the zygotes was placed; *b*, the lid with O-ring; *c*, and three screw-holes; *d*, to press the cover slide against the surface. *H*, Hole for the wooden shaft. The hardness of the steel was 68 Rockwell. The sledge hammer was made for the Municipal Tramcar Company in Oslo about 50 yr ago and specimens are no longer available.

cytoarchitecture in defined directions. Our experimental arrangements are primitive but we hope this note will bring us in contact with people who can suggest more appropriate methods, which enable measurements and calculation of the velocity, amplitude and shape of the shock wave.

Differential survival of skin and heart allografts in radiation chimaeras provides further evidence for Sk histocompatibility antigen

CERTAIN inbred mice, lethally irradiated and inoculated with bone marrow and spleen cells from F1 hybrids, reject donor-strain skin grafts although they are permanent haemopoietic chimaeras¹⁻³. After rejection their serum is specifically cytotoxic *in vitro* for donor-strain epidermal cells but not lymphoid cells⁴, and their leukocytes are stimulated specifically in mixed cultures by donor-strain epidermal cells but not leukocytes⁵. Thus epidermal cells contain distinctive surface alloantigens (skin-specific or 'Sk' alloantigens) which have been suggested to function *in vivo* as histocompatibility antigens. If this is correct, the rejection of donor-strain skin grafts by persistent chimaeras could be explained as a loss of 'self-tolerance' to donor-strain Sk antigens by grafted haemopoietic cells as they proliferate in allogeneic recipients in the absence of these antigens^{1,2}. This interpretation is strengthened because donor-strain skin grafts are not rejected if radiation chimaeras receive donor-strain Sk antigen in the form of epidermal cell suspensions at the time of marrow restoration and thereafter⁶.

Working with inbred rat strain combinations which differ considerably in the survival of skin and organ allografts, we were attracted to the proposed Sk histocompatibility system because of its potential importance as a model of tissue-specific allograft reactions. For example, by analogy with the rejection of skin allografts in the face of persistent haemopoietic chimaerism, the rejection of skin allografts in situations where heart transplants survive indefinitely might result from alloantigens present in skin but absent from heart tissue. Alternately, the differential survival of skin and organ allografts might depend on non-specific differences in their mode of transplantation; natural vascularization and prolonged ischaemia compared with prompt surgical anastomosis, quantitative differences in graft antigenicity, different routes of sensitization and so on.

Previously we attempted to minimize non-specific differences between skin and heart transplants by grafting neonatal heart fragments subcutaneously⁷. Such allografts were rejected acutely like skin allografts, even though surgically

anastomosed heart organ allografts from the same donor strain survived indefinitely^{8,9}. Although this gave no evidence for Sk histocompatibility antigens in rats, they were not ruled out. Moreover, reports that surgically anastomosed skin allografts were rejected acutely in a rat strain combination where kidney allografts survive indefinitely^{10,11} suggested the presence of Sk antigens.

The ability (of J. S. L.) to anastomose organ transplants in mice has facilitated comparison of the survival of surgically anastomosed with naturally vascularized allografts in mouse strain combinations where Sk histocompatibility antigens are presumably operative. As in our experiments with rats, our rationale was to control the non-specific factors in grafting different tissues to assess the importance of tissue-specific factors. We now report the first results of our experiments with heart allografts in mouse radiation chimaeras that reject donor-strain skin allografts while remaining permanent haemopoietic chimaeras.

We produced Sk-reactive radiation chimaeras as described by Boyse *et al.*¹, by exposing C57Bl/6 (B6) mice to 750r whole-body X-irradiation and then inoculating them intravenously with about 50×10^6 (B6 \times A)F1 hybrid spleen cells. As controls for the effects of irradiation we inoculated other similarly irradiated B6 mice with B6 spleen cells. After 11-12 weeks we sent citrated blood samples from the presumed B6/B6 \times A chimaeras to Dr E. A. Boyse's laboratory for H-2 typing of erythrocytes¹. One to three weeks later (that is, 12-15 weeks after irradiation and cell restoration) we challenged those mice with clear evidence of B6/B6 \times A chimaerism and the B6/B6 controls with various types of strain A test grafts. All the skin grafts were transplanted orthotopically to the thorax and evaluated in terms of grossly observable epithelial survival as described by Billingham¹². Since it is necessary to use perinatal donors to obtain heart fragments that acquire assayable pulsatile activity⁷, in one series skin grafts were taken from the newborn mice that provided the heart fragments in order to control for any possible reduced immunogenicity of neonatal tissue. Moreover, 2-mm diameter "mini"-sized grafts were used with the intention of approximating the tissue antigen dosage of the heart fragments. Adult heart organs were transplanted heterotopically to the abdomen as described by Corry *et al.*¹³; newborn heart fragments were transplanted subcutaneously to the ear as described by Fulmer *et al.*⁷. Both types of heart grafts were monitored electrocardiographically as well as grossly and rejection was defined as permanent cessation of electrical activity.

Table 1 shows B6/B6 controls rejected both types of skin and heart test grafts acutely. Indeed, these survival times are similar to those for comparable test grafts in intact non-irradiated B6 recipients, indicating that there were no apparent residual effects of radiation. In contrast, there was a striking difference in the fate of the skin and heart test grafts in the chimaeras. The chronic rejection of the skin grafts verifies the observation of Boyse *et al.*^{1,2} No heart test graft

TABLE 1 Survival of skin and heart test allografts in radiation chimaeras and controls

Type of strain A test graft	Number	B6/B6 controls MST \pm s.d.*	Test graft survival (d) in:			
			Range	Number	B6/B6 \times A chimaeras MST \pm s.d.	Range
Adult donors						
skin	7	8.7 \pm 1.1	8-10	10	20.2 \pm 1.4	14-36
heart organ	8	9.0 \pm 1.4	7-12	5	(66+†, 70+†, 146†, 162†, 175†)	
Newborn (0-48 h-old) donors

§ 2-mm diameter as opposed to the 15-mm diameter adult skin grafts.

recipient has rejected its test graft so far, although two died with surviving grafts. Three months after skin grafting, and well after rejection of the last test graft, we again sent blood samples to Dr Boyse for tissue typing. In every case but one, chimaerism had persisted in spite of the donor-strain skin allograft rejection. Moreover, 2 months after heart grafting, all recipients, when challenged, rejected strain A skin test grafts without discernable effect on preexisting heart grafts which, as just indicated, are still surviving.

We draw two conclusions from the differential survival of skin and heart allografts in our chimaeras. First, in the strain combination tested there is no evidence that mouse heart tissue possesses distinctive histocompatibility alloantigens analogous to Sk. It would, however, be unsafe to conclude that such antigens are not present in heart cells. Even in the case of Sk antigens a serological anti-Sk response has been demonstrated in the absence of graft rejection⁴, as is also the case in the H-Y¹⁴ and Θ ¹⁵ incompatibility systems. Second, the case for Sk functioning as histocompatibility antigen is strengthened, particularly by the differential survival of the newborn skin and heart fragment allografts. Here, where a deliberate attempt was made to graft skin and heart tissue under comparable non-specific conditions (a strategy for revealing the possible contribution of tissue-specific factors), the differential survival observed with the conventional skin and heart organ allografts from the adult donors was maintained.

Our results provide further evidence the Sk antigen can function as histocompatibility antigen. However, they do not rule out an important role for non-specific factors^{8,9} in acute skin allograft rejection because the roles of tissue-specific and non-specific factors are not mutually exclusive. The only definitive way of determining the relative *in vivo* importance of anti-Sk immunity may be through the creation of a congenic resistant line of mice differing from an inbred strain only at the presumed Sk locus.

We thank Dr E. A. Boyse of the Sloan-Kettering Institute for encouragement, suggestions and cooperation. We particularly thank Ms Chika Iritani of his laboratory for carrying out H-2 typing tests. Pharmacological evidence related to the existence of two sodium channel gating mechanisms

IN 1952, Hodgkin and Huxley¹ proposed the now classical differential equation that has become the accepted mathematical model for describing action potentials. In this equation there are three probability factors, m , n and h , which depend on transmembrane potential and time. Conceptually these probability factors are often considered to represent three field-dependent molecular gating mechanisms that mediate ionic flow through two transmembrane channels. The m and h gates mediate sodium currents and the n gate controls potassium flow. Electrical evidence has been presented for a molecular rearrangement associated with sodium activation (for example, m gate opening)². This evidence is based on the detection of transient electrical currents in the axon membrane which are hypothesised to represent rearrangement of molecular dipoles.

Pharmacological evidence for these gating mechanisms is scanty. Purified conylactis toxin³ has been reported to interfere with sodium inactivation⁴, but only in invertebrates (personal communication from B. I. Shapiro), thus restricting its usefulness and generality. Tetrodotoxin and saxitoxin are believed to bind to a common site on the sodium channel^{5,6}, but so as to decrease maximum sodium permeability, \bar{g}_{Na} , rather than affecting any of the probability factor equations. The difficulty of synthesising active derivatives of these complex alkaloids limits their usefulness as biological probes of structure-activity.

We have been investigating neurotoxins that act specifically on action potentials in vertebrates and may therefore be useful as probes of the nervous conduction mechanism in higher animals⁷. The toxins are components of the venom of the scorpion *Heterometrus gravimanus*. Two active fractions have been isolated one of which seems to delay sodium inactivation while the other exerts an effect which may be consistent with an abnormally persistent sodium activation.

Lyophilised venom of *Heterometrus gravimanus* (Sigma) was fractionated on a column of Whatman 23 CM-cellulose as shown in Fig. 1. Seven peaks led absorption above back-

FIG. 1 Chromatogram of *Heterometrus gravimanus* venom on carboxymethyl-cellulose (Whatman 23). Absorbance was measured at 280 nm.

FIG. 2 Action potentials recorded at the node of Ranvier from sciatic nerve fibres of *Xenopus laevis* after application of venom or venom fractions. Procaine (1%) was used to block biphasic potentials. The vertical markers represent a scale of approximately 20 mV. *a*, Crude venom ($20 \mu\text{g ml}^{-1}$); *b*, fraction D from chromatographed venom ($1 \mu\text{g ml}^{-1}$); *c*, fraction C from chromatographed venom ($1 \mu\text{g ml}^{-1}$).

ground at 280 nm, and all peaks gave positive tests for protein by the method of Lowry *et al.*⁸ Table 1 gives this data in more detail. It is interesting that fractions C and D, the only two that affect action potentials, each represent less than 1% of the venom by weight.

Action potential responses were obtained by a technique described earlier^{9,10}, in which single medullated nerve fibres from the sciatic nerve of *Xenopus laevis* were recorded using a single air gap technique. In some experiments, 0.11 M KCl was used to block the biphasic action potential on one side of the air gap and in other experiments procaine was used. Continuous flow of fluid over active nodes in the opposite pool adjacent to the air gap was maintained relatively constant by means of gravity flow from a Mariotte flask.

When crude venom was applied to a node for several minutes in a dose of $20 \mu\text{g ml}^{-1}$, repetitive action potential spikes resulted (Fig. 2*a*). There was no long delay in the inactivation process as had been reported for the venom of *Lieurus quinquestriatus*¹¹. The effect was irreversible. However, when the venom was first dialysed against Ringer solution for 4 h and then applied to the nerve fibre, no repetitive spikes were seen, but there was a large and irreversible delay in sodium inactivation when venom was applied in a dose of $50 \mu\text{g ml}^{-1}$ (similar to Fig. 2*b*). Twenty to thirty minutes after application of venom, the delay was several hundred milliseconds. The difference between the results of experiments conducted before and after dialysis suggested that there was more than one venom component, each acting by a different mechanism. At least one of these components would be either readily dialysable or absorbed

by the membrane. Addition of 10mM tetraethylammonium chloride (TEA) to the perfusion medium failed to stop either the repetitive spikes or the sodium inactivation delay, giving further evidence that the sodium channel was the target of the venom. TEA selectively blocks potassium conductance increases¹².

Subsequent tests of fractionated venom components gave the following results. First, only fractions C and D affected the action potential. Fig. 2*b* shows an action potential from a nerve fibre poisoned by fraction D. There is an irreversible delay in sodium inactivation at concentration of $1 \mu\text{g ml}^{-1}$, similar to that observed in the crude venom of *Lieurus quinquestriatus*¹¹. With fraction C (Fig. 2*c*), however, the time course of voltage increases and decreases during the action potential was relatively unaffected until the membrane potential returned to about 20 mV above the resting level. Recovery was then characterized by a persistent plateau lasting many milliseconds. Since the initial time course of sodium inactivation seemed to be essentially unchanged, we concluded that persistent sodium activation may have been involved. This conclusion is reinforced by observations in which the crude venom of *Centroides sculpturatus* was found to prolong sodium activation¹³. Increasing the dosage or prolonging the exposure only increased the length of the trailing plateau and did not affect its potential level. TEA (10 mM) failed to abolish this plateau, although a slower spike decay was apparent, as would be expected from an action potential without the delay potassium permeability change. This effect was also irreversible.

At this stage, we have no explanation for the repetitive spikes produced by crude venom, although it may be the result of combined interactions of two or more venom components with the nerve membrane.

Positive results in the Lowry test suggested that the active components of the venom were protein. Preliminary studies on sodium dodecyl sulphate gel electrophoresis indicated molecular weights of less than 10,000, and the high NaCl molarity required to elute these fractions from the CM-cellulose indicated a positively charged protein. These properties are reminiscent of those possessed by the cholinergic neurotoxins of Elapid snake venoms. (Detailed biochemical studies will be reported later.)

TABLE 1 Protein content of each peak estimated by Lowry's method

Fraction	Absorbance (750 nm)	Est. conc. ($\mu\text{g/ml}^{-1}$)	% of Venom (weight)
A	>0.500	>140	>7.0
B	0.329	90	3.6
C	0.115	33	0.66
D	0.170	48	0.96
E	0.152	43	1.29
F	0.150	43	0.43
G	0.249	71	2.85

The instrument for measuring absorbance was calibrated with bovine serum albumen as standard.

Our results may be significant for two reasons. First, they offer possible pharmacological evidence, for two molecular gating mechanisms that may be a biochemical correlate of the *m* and *h* probability factors originally derived by Hodgkin and Huxley¹. Second, and perhaps more important, these neurotoxins have potential application as previously unavailable biochemical probes of the sodium channel. A parallel situation existed with the cholinergic neurotoxins of the Elapid snake venoms in that they allowed the first widely acceptable isolations and partial biochemical characterisations of the acetylcholine receptor.

Part of this research was used in fulfillment of the thesis

requirements at New College, Sarasota in 1973. We thank Dr Jon Culbertson for sponsoring this study.

Absorbance changes induced by blue light in *Phycomyces blakesleeanus* and *Dictyostelium discoideum*

BLUE and near ultraviolet light controls several metabolic and physiological processes in organisms ranging through bacteria¹, fungi² and algae^{3,4} to vascular plants⁵ and animals^{6,7}. The similarity of the action spectra of these various light-induced responses (all have action maxima at about 470 nm) suggests a common photoreceptor pigment system which controls these different cellular processes. We have looked for light-induced absorbance changes that might be related to such a pigment system.

Our initial work involved *Phycomyces blakesleeanus* because extensive investigations had been made of the blue-photoreceptor pigment in this organism². (This pigment resides both in the sporangiophores where it controls the phototropic response² and in the mycelium where it controls sporangiophore initiation⁸.) Mycelial mats were used rather than sporangiophores because of the greater ease of collection and preparation, and because the large vacuoles in the sporangiophores made them less promising material for spectrophotometry. We also used cell suspensions of *Dictyostelium discoideum*.

Light-minus-dark difference spectra were measured with a single-beam spectrophotometer on line with a PDP8/I computer. The absorption spectrum of the sample was measured (20 s per scan) just before and 30 s after a 30 s irradiation with actinic light obtained with a xenon lamp in conjunction with interference filters (12 nm half-bandwidth). The same timing sequence was used between irradiation and measurement in all experiments. The kinetics of decay of the light-induced absorbance changes after irradiation were measured with an Aminco-Chance dual-wavelength spectrophotometer.

The light-minus-dark difference spectrum (that is, the difference between the absorption spectrum measured after irradiation and that measured before irradiation) of a fresh

sample of *P. blakesleeanus* due to irradiation with 470 nm actinic light shows bleaching at 445 nm and an increase in absorbance at about 430 nm (Fig. 1a). If the sample was allowed to become anaerobic in the cuvette before irradiation, there was no bleaching at 445 nm but the absorbance increase at 430 nm remained (Fig. 1b). Both these absorbance changes decayed in darkness with a half-time of about 70 s.

Blue light at about 470 nm contains the most effective wavelengths for eliciting these absorbance changes. These wavelengths are also the most effective for the physiological blue light responses of *P. blakesleeanus*². Dense mycelial mats, however, are not suitable for measurement of an action spectrum of the photosensitive absorbance change; the response is not sufficiently stable for repetitive excitation of a given sample with different wavelengths and the preparation techniques are not sufficiently reproducible to permit fresh samples for each actinic wavelength.

Berns and Vaughn⁹ reported different light-induced absorbance changes with mycelial mats of *P. blakesleeanus*: irradiation with 345 nm actinic light caused an absorbance change between 460 and 345 nm (which could have been due to bleaching at 345 nm or to an increase in absorbance at 460 nm) of about 0.04 which persisted for several minutes. We tried to reproduce these measurements using a filter double-beam spectrophotometer comparable with that used by Berns and Vaughn, but found no light-induced absorbance differences between 460 and 345 nm greater than the noise level of the measurement (0.002).

Cell suspensions of *D. discoideum* were also examined for light-induced absorbance changes. The light-minus-dark difference spectrum of a fresh sample of cells taken near the end

FIG. 1 Light-induced absorbance changes in *P. blakesleeanus*. A carotenoid deficient strain of *P. blakesleeanus* (C-2) was grown for 5 d in stationary culture after inoculation with heat-shocked spores of the medium described by Carlile¹³. The mat of mycelium was lifted from the culture flask and plugs were cut with a cork borer to fit the bottom of a cylindrical vertical cuvette. The sample was about 3 mm thick and represented an absorbance of about 3 at 425 nm. Actinic light was 3 mW cm⁻² at 470 nm. *a*, Light-minus-dark difference spectrum of a freshly prepared sample. *b*, Light-minus-dark difference spectrum of a sample permitted to go anaerobic in the cuvette before the measurements.

Fig. 2 Light-induced absorbance changes in *D. discoideum*. A strain A3 of *D. discoideum* able to grow in axenic culture was grown in liquid medium and collected as previously described¹⁰ while in late exponential growth phase. The sample consisted of a cell suspension (4×10^8 cells ml⁻¹) approximately 3 mm thick which represented an absorbance of about 3 at 425 nm. *a*, Light-minus-dark difference spectrum of a freshly prepared sample. *b*, Light-minus-dark difference spectrum of a sample permitted to age for several hours before the measurements.

of log phase growth (Fig. 2*a*) shows bleaching at 445 nm and an increase in absorbance at about 430 nm. If the cells aged for several hours before the experiment, there was no bleaching at 445 nm and the increase in absorbance at 430 nm was generally somewhat greater than without ageing (Fig. 2*b*). In the latter case, slight bleaching was also observed near 410 nm. The light-induced absorbance changes in cells of *D. discoideum* (Fig. 2) were essentially the same as those in the mycelium of *P. blakesleeana* (Fig. 1).

Two different light-induced absorbance changes can be measured in cells of *D. discoideum*: one is a small rapidly decaying absorbance increase at 410 nm which can be induced by wavelengths as long as 600 nm¹⁰; the other is a larger, more slowly decaying absorbance increase at 430 nm (Fig. 2) which is induced only by wavelengths shorter than 520 nm. The small absorbance increase (about 0.001) at 410 nm, induced when cells of *D. discoideum* are irradiated with blue as well as yellow light, did not contribute to the difference spectra shown in Fig. 2. The small absorbance change decays in the dark with a half-time of 7 s and thus decayed to a negligible level during the 30 s between the irradiation and the start of the spectral scan. The light-induced absorbance changes shown in Fig. 2 for *D. discoideum* cells decay in the dark with a half-time of about 70 s, as did the similar changes in *P. blakesleeana*, and thus persist long enough to be measured by the spectral scan after irradiation. The pigment which responds to the longer wavelengths of light has been extracted from *D. discoideum* cells and purified as a high molecular weight haem protein¹¹. This pigment appears to be the photoreceptor pigment for the photoactive response of *D. discoideum*. The pigment which responds only to the shorter wavelengths of light ($\lambda < 520$ nm) has been observed

both in cells of *D. discoideum* (Fig. 2) and in the mycelium of *P. blakesleeana*. Its physiological function in *D. discoideum* is unknown (there may be photoresponses controlled by the blue-photoreceptor pigment which we are not aware of in *D. discoideum*) but it is a promising candidate for the blue-photoreceptor pigment which is manifest in so many different organisms.

An approximate action spectrum for the light-induced absorbance change in aged cells of *D. discoideum* (Fig. 2*b*) was determined by measuring the absorbance change induced by equal intensities (3 mW cm⁻²) of monochromatic actinic light. A plot of the magnitude of the light-induced absorbance change as a function of the wavelength of actinic light (Fig. 3) shows that the action is maximal at about 465 nm and absent beyond 520 nm. This action spectrum for the light-induced absorbance increase at 428 nm is consistent with those for the various physiological responses which are attributed to the blue-photoreceptor pigment.

If cells of *D. discoideum* are broken gently in a Dounce homogenizer, the photoresponsive pigment sediments with the mitochondrial fraction collected by differential centrifugation between 6,000 and 10,000*g*. If the cells are broken more thoroughly by passage through a Ribi press, the photoresponsive pigment is found in the soluble supernatant from a 1 h centrifugation at 144,000*g*. The absorption spectrum of the soluble extract after cell breakage in the Ribi press (Fig. 4, curve D) shows primarily reduced cytochrome *c*. The spectrum measured after irradiation (curve L) shows small light-induced changes which are seen best at higher sensitivity in the L-D difference spectrum. The light-induced absorbance changes in the soluble extract include an absorbance increase in the 560 nm region and a larger, sharper increase at 425 nm, both indicative of a photoreduction of a *b*-type cytochrome.

The photoactive pigment system apparently consists of a photoreceptor pigment, possibly a flavin, which absorbs maximally at about 465 nm, and a photoresponsive pigment, a *b*-type cytochrome, which increases in absorbance maximally at 428 nm *in vivo* and at 425 nm *in vitro*. In the fresh tissue the photoreceptor pigment may also induce bleaching at 445 nm which could be due to the oxidation of an *a*-type cytochrome. The proposed flavin-mediated photoreduction of a *b*-type cytochrome in soluble extracts suggests a cyto-

Fig. 3 Action spectrum for the light-induced absorbance change in *D. discoideum*. Aged samples were prepared as described in Fig. 2. The cells were irradiated with equal energies (3 mW cm⁻²) of monochromatic actinic light and the light-minus-dark difference spectra were recorded for the different wavelengths of actinic light. A fresh sample of cells was used for each actinic wavelength since the response tends to decay with repeated excitation. The magnitude of the light-induced absorbance change measured between the peak at 428 nm and the minimum at 411 nm is plotted as a function of the wavelength of actinic light.

Fig. 4 Light-induced absorbance change in a cell-free extract of *D. discoideum*. Cells were grown as described in Fig. 2 to maximum stationary phase of growth at 1.2 to 1.6×10^7 cells per ml, washed, and concentrated to 10^8 cells per ml by centrifugation. The cells in this suspension were broken in a Ribi press at 12,000 pounds inch $^{-2}$ and the subcellular particles eliminated by centrifugations at 1,000g for 5 min and 12,000g for 30 min. The soluble supernatant was then collected from a centrifugation at 144,000g for 60 min. Spectra of this soluble supernatant were measured at 22° C in darkness (D) and immediately after exposure to 3 mW cm $^{-2}$ actinic light at 470 nm (L). The light-minus-dark difference spectrum (L-D) is also presented at an eight-fold increase in sensitivity (plotted directly by the computer).

chrome b_2 -like pigment with the flavin and haem prosthetic groups on the same protein molecule 12 . These speculations remain to be confirmed but the experimental system is available.

We have not obtained a cell-free system from *P. blakesleeana* which shows the photoinducible absorbance changes but these experiments are continuing. We believe, however, that a common blue-photoreceptor pigment is present in widely diverse types of cells and that cells of *D. discoideum* may be a fortuitous source of the pigment.

This work was supported by a grant from the US National Science Foundation. We thank Dr M. Delbrück for the C-2 strain of *P. blakesleeana*, Sandra Swarbrick for technical assistance and Dr W. F. Loomis, jun. for interest and helpful discussions.

Actin in the alga, *Chara corallina*

ACTIN and myosin from muscle combine to form filaments with a distinctive arrowhead appearance 1 . Filaments from several lower organisms $^{2-5}$ and from cells other than muscle in higher animals $^{6-9}$ also react with muscle myosin or its subfragments to produce arrowhead filaments. This ability to bind muscle myosin has become accepted as a test for the identification of the filaments as actin. Its validity is supported by the chemical similarities between those actins which have been further characterised $^{6,8-13}$, and by the need for the myosin binding sites to be quite specifically positioned and oriented for the arrowhead effect to arise 14 . A filament reacting with heavy meromyosin subfragment one (S_1) has now been detected in cells of the green alga, *Chara corallina*.

Internodal cells about 70 mm in length were centrifuged in a bench centrifuge at 600g for 5 min. Such treatment

Fig. 1 a, A simple filament without S_1 treatment or, as in this case, after treatment with S_1 and ATP. b, Filament after treatment with S_1 . In places an arrowhead effect is seen; elsewhere the surface of the filament is irregular. Bar = 100 nm.

displaces the flowing endoplasm to the centrifugal end of the cell, which can then be cut off and discarded. The remainder of the cell (that part containing stationary cortical cytoplasm only) was squeezed to expel its contents. The contents of 12 such centrifuged cells were pooled and spun at 200g for 2 min. The pellet was resuspended in 50 μ l of 150 mM KCl, 10 mM trisodium EDTA, buffered at pH 7.0 with 10 mM morpholinopropane sulphonic acid. After 10 min at room temperature, the preparation was again spun at 200g for 2 min and the pellet discarded. In some experiments, an S_1 preparation from rabbit skeletal muscle was added either at the resuspension stage or to the final supernatant. The mixture was then kept at room temperature for between 10 and 60 min. All preparations were negatively stained with 1% uranyl acetate on carbon-coated specimen grids.

In the absence of the S_1 preparation, the supernatant contained simple filaments of the type shown in Fig. 1a. After S_1 treatment, filaments were found which in places had the distinctive arrowhead appearance of the actomyosin complex (Fig. 1b). If 1 min before transfer to the grid, neutralised ATP was added to a final concentration of 1 mM, the arrowhead effect disappeared (Fig. 1a). No arrowhead filaments could be found when the S_1 preparation was examined alone.

Compared with the results obtained in parallel experiments with rabbit actin, the algal filaments showed, in so far as it could be judged, less regular arrowheads. Lengths of filament without arrowheads showed an irregular, roughened surface (Fig. 1b), again quite distinct from their appearance without S_1 or after ATP treatment. Moreover, whereas stored S_1 retained its ability to decorate rabbit actin, fresh S_1 was needed to give convincing decoration of the algal filaments. These two observations may be a reflection of differences in S_1 -binding ability between the algal and rabbit filaments, although further studies will be needed to establish this.

For the reasons summarised above, the formation of such arrowhead complexes is a preliminary, but probably reliable indicator of the presence of actin. The present experiment does not settle its position or function in these cells. In this connection however, microfilament bundles are known in closely related algae¹⁵⁻¹⁷, as well as in the cells of higher plants¹⁸. Unpublished light and electron microscope observations of cells of *C. corallina* have shown that the microfilament bundles are retained with the cortical cytoplasm on centrifugation. These microfilament bundles are believed to be involved in the mechanism of cytoplasmic streaming, and could well be the location of actin within these cells.

I thank G. J. Hudson for gifts of actin and S_1 , E. A. C. MacRobbie for helpful discussions, and Churchill College for a Junior Research Fellowship.

Photoeffects in a flavin-containing lipid bilayer membrane and implications for algal phototaxis

FLAVINS have been implicated as receptor pigments in various plant photoresponses, such as phototropism¹, phototaxis² and chloroplast movement³. It has not yet been possible to prove conclusively the flavin photoreceptor hypothesis in any of these cases, nor has a mechanism been demonstrated by which a flavin could convert a light stimulus into a physiological signal. For the light-induced motor response involved in phototaxis of *Euglena*, we have suggested an electrical type of stimulus transduction by a flavin receptor pigment embedded in a lipid matrix⁴.

We report here light-induced electrical effects in an artificial bilayer membrane of the Mueller-Rudin type⁵ that contains an amphipathic riboflavin derivative. Riboflavin tetrapalmitate was prepared according to the method of Yagi⁶. It was incorporated into an oxidised cholesterol bilayer⁷ by adding it to the membrane-forming solution at a ratio, in the bulk phase, of 1 flavin molecule to 10 cholesterol molecules. The solutions of the aqueous phases (phosphate and citrate buffers or KCl, all 0.1 M) were made up from triply distilled water and ACS grade chemicals. Illumination was with white light from a 500 W tungsten projector lamp and was passed through glass heat filters, at a maximum intensity of 4 kW

Fig. 1 Photocurrent observed as a function of applied potential on illumination of a bilayer lipid membrane containing riboflavin tetrapalmitate with white light (intensity 4 kW m⁻²).

Fig. 2 Photoeffects in the flavin-bilayer membrane as a function of the pH of the aqueous phase.

m^{-2} ($4 \times 10^6 \text{ erg cm}^{-2} \text{ s}$). The photocurrent was recorded with a Honeywell Elektronik 16 strip chart recorder connected to a Keithley 610C electrometer.

Incorporation of the riboflavin tetrapalmitate did not affect the membrane resistance at neutral and slightly acidic pH, and decreased it by a factor of two to three at basic pH values. When normalised to the same peak height, photoresponses observed under the same conditions were very similar, though the magnitude of individual responses fluctuated greatly. We have not yet been able to pinpoint the reason for these variations.

As in all other systems studied so far, no photoeffects occur under completely symmetrical conditions. When an external potential was applied, at pH 6 and 7 we observed the effects shown in Fig. 1. The photoresponse consisted of a transient current decrease on illumination, followed by a return to the baseline and, when the light was turned off, a transient current pulse in the positive direction. This cannot be explained simply as an effect on membrane resistance, since the 'on'-current crosses the zero line and inverts direction transiently. The effect was the same in buffered and in unbuffered solution. From 16 to 70 mV, the peak heights of the response increased linearly with the applied potential.

As Fig. 2 shows, the nature of the photoeffect changed with increasing pH. At pH 8, the transient pulses when the light was turned on and off were still visible, but superimposed on this effect was an increase of the current lasting as long as the illumination, and slowly decreasing to the dark value after the 'off'-pulse had decayed. At pH 9 or higher, the negative 'on'-pulse was no longer discernible. In its place we observed a very rapid increase of current. The 'off'-pulse was still visible and followed by a transient slow decrease of the current below the dark value. At this pH, illumination for more than 5 s irreversibly decreased the membrane resistance.

Because of the above observation, and since the addition of flavins at pH values above 7 increases the current across the membrane even before illumination, we consider it

Fig. 3 Model proposed for the generation of the transient photocurrents at pH 7. BLM, bilayer membrane.

possible that the photoeffects appearing at basic pH values were, at least partly, due to effects on the membrane resistance. We have not yet attempted to substantiate this assumption.

We offer the following preliminary hypothesis to account for the characteristics of the photoeffects at neutral and slightly acidic pH. Illumination polarises the flavin moiety of the chromophore, perhaps through an electron acceptor/donor reaction of an electronically excited state of the flavin with another molecule in the lipid or aqueous phase. The polarised chromophore now interacts electrostatically with water dipoles at the membrane surface that had been pre-oriented by the applied potential. This reorientation of the dipoles corresponds to a transient transport of charges against the applied potential (Fig. 3).

This model accounts for the following observations. (1) The current pulses were transient, and a pulse in the direction of the applied potential appeared when the illumination was removed, that is when the reorienting force was released. (2) No photoeffect was observed without an externally applied potential, and reversal of the polarity of the applied potential changed only the sign of the photoresponse. (3) Increased applied potential increased the magnitude of the photoresponse, since more complete preorientation of the dipoles increased the number of charges which were transported on reorientation. At 70 mV, which was the largest potential we used because of membrane instability at higher

Fig. 4 Light intensity dependence of the flavin-bilayer membrane photoeffects at pH 7 (Δ) and the direct photophobic response of *Euglena* (\circ). The magnitude of both responses was arbitrarily set equal to 100 at the maximum intensity of 2 kW m^{-2} . AU, arbitrary units.

potentials, we had apparently not yet approached saturation effects caused by complete preorientation.

Calculations indeed predict that the triplet excited state of riboflavin tetrabutylate should exhibit a dipole moment which is larger than that of the ground state by a factor of 1.47 (ref. 8).

Our model is similar to that proposed by Ullrich and Kuhn for cyanine dyes adsorbed to one side of a bilayer membrane⁹. It is probably incomplete in that it cannot account for the fact that the 'off'-pulse never reaches the expected same magnitude as the 'on'-pulse. One must assume that an irreversible reaction, probably a photodecomposition of the flavin, occurs in parallel with the dipole orientation process. In agreement with this reasoning, we have observed that under all experimental conditions the photoeffects become smaller when illumination is repeated.

The interpretation of our findings with respect to the mechanism of stimulus transduction in *Euglena* must be speculative, since we have as yet no *in vivo* electrophysiological data. We have suggested previously that in *Euglena*, a physiological signal is generated by means of photoconduction

across a poised oxidation/reduction system. We observe in our bilayer membrane that photoeffects occur with an unbuffered ascorbate gradient across the membrane, but these effects disappear upon buffering. Apparently, the effects are in this case dependent upon a pH gradient rather than a redox gradient. In this context one might note that the acidities of the excited states of flavin have been calculated to considerably exceed that of the ground state¹⁰. Even though this prediction has not yet been tested experimentally, light-induced release of protons might thus provide an alternative mechanism for generation of the photocurrents observed by us.

The light intensity dependence of the bilayer membrane photoresponse at pH 7, and that of the direct photophobic response which *Euglena* exhibits when illuminated¹¹ are identical up to an intensity of 2 kW m⁻² (Fig. 4). This agreement may be fortuitous. At 4 kW m⁻² (a light intensity that we have not reached in measurements of *in vivo* responses of *Euglena*), the magnitude of the bilayer membrane photoeffect falls below an extension of the straight line in Fig. 4.

Spinal interneurone excitation by conformationally restricted analogues of L-glutamic acid

L-GLUTAMIC acid is probably an excitatory transmitter of major significance in the mammalian central nervous system¹. The L-glutamic acid molecule is relatively flexible, and in an attempt to gain some insight into its possible shape(s) during activation of receptors associated with excitation of central neurones, a study was made of four conformationally restricted analogues: (±)-*cis*-1-aminocyclohexane-1,3-dicarboxylic acid ('cyclo-glutamic' acid), ibotenic acid, kainic acid and its dihydro derivative.

Ibotenic acid, an isoxazole isolated from the mushroom *Amanita muscaria*², and kainic acid, a pyrrolidine derivative isolated from the seaweed *Digenea simplex*^{3,4}, have previously been shown to excite central neurones^{5,6}. 'Cyclo-glutamic' acid is an inhibitor of glutamine synthetase⁷. In each of these cyclic compounds the ring restricts rotation about bonds equivalent to the C_α-C_β and/or C_β-C_γ bonds in L-glutamic acid.

The experiments were carried out on spinal interneurones and Renshaw cells of eight cats anaesthetised with pentobarbitone sodium (35 mg kg⁻¹ given intraperitoneally), administering the amino acids electrophoretically from seven barrel micropipettes⁸. Kainic acid, DL-homocysteic acid and L-glutamic acid were purchased from Calbiochem (Los

Angeles). Dihydrokainic acid was prepared by catalytic hydrogenation of kainic acid³ and N-methyl-D-aspartic acid was prepared by methylation of D-aspartic acid⁹. The micropipettes contained the following solutions: 'cyclo-glutamic' acid (1 M, adjusted to pH 7.3 with NaOH), dihydrokainic acid (0.2 M, pH 7), L-glutamic acid (0.5 M, pH 8), DL-

TABLE 1 Approximate potency ranges of excitant amino acids relative to L-glutamic acid, based on the ejecting currents required to achieve equal increases in firing frequency of spinal neurones

Amino acid	Potency range relative to that of L-glutamic acid
Kainic acid	8-80(12)*
N-Methyl-D-aspartic acid	7-18(3)
DL-Homocysteic acid	3-6(6)
Ibotenic acid	2-7(6)
L-Glutamic acid	1(25)
'Cyclo-glutamic' acid	0.7-0.8(3)
Dihydrokainic acid	0.06-0.6(5)

* Number of neurones tested.

homocysteic acid (0.2 M, pH 7.5), ibotenic acid (0.2 M, pH 7), kainic acid (0.1 M, pH 8) and N-methyl-D-aspartic acid (0.1 M, pH 8).

The approximate relative potencies (Table 1) of the amino acids as excitants of neuronal firing were assessed on the basis of results obtained with 17 interneurones and ten Renshaw cells. Kainic acid was more potent than N-methyl-D-aspartic acid, previously the most potent amino acid excitant reported¹⁰. On the other hand, dihydrokainic acid was the weakest excitant of the series. Figure 1 illustrates the effect of kainic acid on the firing rate of an interneurone in comparison with that of L-glutamic, DL-homocysteic and N-methyl-D-aspartic acids. The actions of kainic and N-methyl-D-aspartic acids were relatively slow in both onset and offset, compared to that of L-glutamic acid; this was also apparent with 'cyclo-glutamic', dihydrokainic and ibotenic acids.

An analysis of molecular models indicates that there is a unique juxtaposition of the equivalent ionisable groups in 'cyclo-glutamic', L-glutamic, ibotenic and kainic acids in the

Fig. 1 Comparisons of the excitatory action of L-glutamic acid, DL-homocysteic, N-methyl-D-aspartic and kainic acids on a spinal interneurone. The black horizontal bars indicate times of electrophoretic ejection using the currents indicated (nA).

conformations illustrated in Fig. 2. It therefore seems possible that these amino acids interact with the same receptors. L-Glutamic acid is shown in a partially extended conformation with the C_α-C_β substituents eclipsed and the C_β-C_γ substituents staggered; this and the conformations shown for ibotenic and kainic acid would be expected to be relatively stable forms. The boat form of 'cyclo-glutamic' acid would be, however, less stable than a chair form. The

double bond in kainic acid must play a key role as saturation of this bond yields dihydrokainic acid which is much less potent than the parent compound as an excitant. This double bond, the conformation of which is arbitrarily illustrated in Fig. 2, might bind to a specific site on the receptor or might influence the preferred conformation and/or electronic properties of the neighbouring carboxyl group.

Fig. 2 Conformations of glutamic, ibotenic, kainic and 'cyclo-glutamic' acids in which the ionisable groups occupy the same absolute positions.

The ionisable groups of L-aspartic acid, also probably an important excitatory transmitter in the spinal cord¹, and of N-methyl-D-aspartic acid cannot match those illustrated in Fig. 2 for L-glutamic acid and its analogues. It is thus proposed that excitation by L-glutamic acid and L-aspartic acids results from preferential interaction by these two amino acids with different receptors. L-Glutamic acid might interact with 'glutamic acid preferring' receptors in partially extended conformations (approximating that shown in Fig. 2), and perhaps also with 'aspartic acid preferring' receptors in partially folded conformations. On the other hand, L-aspartic acid may interact only poorly, or not at all, with 'glutamic acid preferring' receptors because the carbon chain of L-aspartic acid is one atom shorter than that of L-glutamic acid.

The proposal provides one explanation of the differences in the relative potencies of L-glutamic and L-aspartic acids as excitants of Renshaw cells and dorsal horn interneurons^{2,3}. These neurones may have different populations of receptors for excitant amino acids, as a result of innervation of the interneurons, but not the Renshaw cells, by primary afferent fibres likely to release L-glutamic acid as a transmitter⁴.

Further studies with conformationally restricted analogues of L-glutamic acid, which may have different affinities for 'aspartic acid preferring' receptors compared to L-glutamic acid, may aid in assessing whether there is overlap between 'glutamic acid preferring' and 'aspartic acid preferring' receptors, though the discovery of a selective antagonist for either receptor would be of more value.

Ibotenic acid and 'cyclo-glutamic' acids were gifts from Dr C. H. Eugster (Zürich) and Dr A. Meister (New York) respectively.

Atmospheric pressure during incubation and post-hatch behaviour in chicks

DOMESTIC chicks are widely used as convenient experimental animals, but their use has a major drawback; one batch is frequently quite unlike another. Chicks hatching one week may, for example, be behaviourally sluggish whereas chicks hatching another week may be hyperactive. Striking differences have been found in a wide variety of behavioural and biochemical measures¹⁻³.

Some batch variation may be attributable to genetic differences in the parents but marked variability is still obtained when eggs are taken from the same flock. The quality of the eggs may change as the hens grow older but this factor could hardly explain the great fluctuations in responsiveness from one week to the next. Differences might be due to variation in the time between laying and incubation of the eggs. Batch differences, however, persist when this time is kept constant and all the eggs are kept at the same temperature before incubation.

The weather is, however, one factor which does change markedly and uncontrollably from week to week. While temperature and relative humidity are unlikely to be responsible for inter-batch variation, since they are kept within narrow limits during incubation, atmospheric pressure is not usually controlled and might be an important variable. I have therefore examined the association between atmospheric pressure and a variety of measures obtained in a long experiment on imprinting in which, for many weeks domestic chicks were incubated, reared and tested under the same conditions. The results of the analysis suggest that the chick embryo is, indeed, sensitive to atmospheric pressure at a certain stage in its development.

Ten batches each consisting of 90 fertile eggs from a broiler strain (Ross Chunkies) were collected at intervals from Ross poultry Products at Fornham All Saints, Suffolk. The eggs were incubated in a Western Turkeyette incubator kept at 37.5-37.7° C. The temperature was controlled by a sealed mercury contact thermometer. The eggs were transferred 18-19 d after the onset of incubation to a still-air Curfew incubator where they hatched. Throughout incubation eggs were kept in the dark and were in contact with other eggs^{4,5}. The chicks also hatched in the dark and were kept in a dark incubator until the time of the experiment. The mean post-hatch ages at the time of the experiments and the numbers of chicks used in each experiment are shown in Table 1.

Fig. 1 The correlation between barometric pressure and the approach activity of day-old chicks plotted against the day of incubation from which pressure readings were taken. Spearman correlation coefficients are given. *a*, Onset of incubation; *b*, hatching; *c*, testing.

The chicks were placed in running wheels facing flashing, rotating lights⁶. Typically day-old chicks approach such a light after a short delay and do so with increasing vigour. They learn the characteristics of the light to which they are exposed and their social preferences are increasingly restricted to the familiar object (imprinting). In these experiments the chicks were exposed for a total of 72 min and later were given a choice between the familiar object and a novel one in an apparatus which provided a quantitative measure of each bird's preference. The principal behavioural measures examined were: latency—the time taken from the beginning of the period of exposure to the moment when approach towards the flashing light began; approach activity—the counts of approach activity in the 20 min after each chick had first started to approach; and preference for familiar—the extent to which, in a choice test, the birds preferred the light

to which they had been previously exposed. Data for each batch are shown in Table 1. Noon barometric pressure readings were obtained from a meteorological station at Oakington, Cambs. which is 4.5 km from the laboratory and 13 m lower. During the period of the experiment the maximum recorded was 1,036 mbar and the minimum 984 mbar.

Barometric pressure was most strongly associated with approach activity. Figure 1 gives coefficients for correlations, between mean approach activity and barometric pressure, plotted against the day of incubation on which pressure was recorded. On the twelfth day of incubation, the correlation was negative and highly significant ($P < 0.01$); the lower the pressure, the more active were the birds when their approach scores were measured on the first day after hatching. The correlation was positive, though not as striking ($P < 0.05$), when pressure readings were taken from a few days before the onset of incubation. While this might be important, the pattern of weather at the time of the experiments was such that barometric pressure recorded 2 d before the onset of incubation was negatively correlated with pressure 12 d after the onset (Spearman $r_s = -0.697$, $P < 0.05$). Latency was not correlated with pressure at any time nor was preference for familiar. Another weather variable, relative humidity, which might conceivably be important, was not correlated at any time with approach activity. Hatchability, the mean of which was $84.52 \pm 1.90\%$, was not correlated with pressure. The median length of incubation was, however, positively correlated with pressure on the twelfth day of incubation ($r_s = 0.707$, $P < 0.05$); the higher the pressure, the longer the time taken from the onset of incubation to the peak period of the hatch. The length of incubation might have influenced activity since all the birds were tested at the same time in relation to the onset of incubation, and post-hatch age and approach activity are positively correlated ($r_s = 0.632$, $P < 0.05$). The activity of the chick embryos, however, could easily have affected their hatching behaviour. If the embryos were sluggish they would be expected to take longer over the highly energetic process of hatching. It seems likely that this was the case as the correlation between pressure and approach activity was stronger. But the matter can only be settled by direct experiment.

One qualification that must be made is that when a large number of correlation coefficients are calculated, a certain proportion of them would be expected to reach the arbitrary levels of statistical significance on a chance basis. Nevertheless it does seem probable that a causal link existed between atmospheric pressure in the second half of incubation and the chicks' subsequent activity. If so, what could the link have been? Possibly the slight effects of pressure on the concentrations of oxygen and carbon dioxide dissolved in the blood are

TABLE 1 Behavioural measures from ten different batches of domestic chicks.

Date of hatching (1973)	Number tested	Post-hatch age at experiment (h)	Latency (s)	Approach activity (Counts/20 min)	Preference for familiar (cm)
March 7	10	22.2 \pm 0.3	174.8(76.9–817.7)	207.3 \pm 54.8	22.9 \pm 13.0

May 22	11	20.2 \pm 0.6	112.0(31.2–192.8)	216.9 \pm 47.8	–2.2 \pm 12.7

Means and standard errors are given except for latency for which medians and interquartile ranges are used. In measuring approach activity four counts were obtained for each revolution of the running wheel. The preference for the familiar was the maximum distance travelled from the midpoint between the familiar light and a novel one. Each chick was placed in a specially geared wheel in which the bird's movements carried it away from the object which it tried to approach. When a chick has been carried sufficiently close to the less preferred light, it usually turned around and attempted to approach that one⁷. A negative score means that a chick attempted to approach the novel stimulus.

critical at a particular stage in the development of the chicks' central nervous system. Hatchability is reduced when eggs are incubated at high altitudes and may be improved by increasing the partial pressure of oxygen⁷. The range of barometric pressure in the experiment reported here, however, corresponded to a difference in altitude of less than 450 m and, of course, pressure fluctuated. Furthermore no association was found between pressure and hatchability. The results certainly suggest that it would be worthwhile examining experimentally the effects of small transient changes in pressure on measures which are more sensitive than the percentage of eggs that hatch. Whatever the outcome of such analysis, the control of pressure may remove one of the irksome sources of differences between batches of chicks.

Behavioural and biochemical details of the experiment reported here will be published elsewhere. I thank Miss J. B. Jaekel for assistance and Drs. G. Horn, and R. Oppenheim, and Miss M. A. Vince for their comments on this manuscript. The work was supported by a grant from the Science Research Council.

Nickel accumulation by *Hybanthus floribundus*

ACCUMULATOR plants are known for many naturally-occurring chemical elements¹. The term 'accumulator plant' is used here to describe plants which have dry-weight elemental concentrations greater than either the associated substrate or 'normal' plants. Much work has centred on copper², zinc³ and selenium⁴ accumulators but little attempt has been made to explain the rationale of elemental accumulation. It is usually considered a 'tolerance' mechanism⁵, and only recently has the functional or essential role of these elements been suggested⁶.

Hybanthus floribundus is an Australian shrub species which accumulates nickel and cobalt with modal levels of 5,000 p.p.m. and 100 p.p.m. respectively, in leaf tissue⁷. Two zinc accumulating *Hybanthus* varieties have also been discovered in the northern savanna zone of Australia.

H. floribundus embraces several sub-species or ecotypes, (to be fully described elsewhere), and has an insular or disjunctive distribution across the southern part of Australia. The three nickel accumulating ecotypes, however, are re-

stricted to a broad belt in Western Australia, which extends from Ravensthorpe near the southern coast, to Agnew, 450 miles to the north. One of these varieties (*H. floribundus* ssp. *curvifolius*) is the subject of detailed distribution and biogeochemical studies in the central part of the belt⁸. The habitat of this shrub is characterised by nickeliferous soils which are defined here by nickel levels in excess of 400 p.p.m. (water-soluble nickel varies around 10 p.p.m.) These soils are often lateritised and result in low calcium levels (less than 4,000 p.p.m.) and a pH range from 5.0 to 6.9. The associated plant species are xeromorphic *Acacia* and *Eucalyptus* trees, and *Eremophila* shrubs. The *Hybanthus* shrubs are conspicuous by their apparent lack of xeromorphic adaptation to a climate which becomes increasingly arid towards the continental interior. This feature has been noted by others⁹.

TABLE 1 Nickel concentrations in soil and various parts of *H. floribundus*

Entire plant	Nickel (p.p.m.)	
	Dry weight	Ash weight
Whole leaf	6,542	130,000
Photosynthetic stem	5,490	132,000
Lower woody stem	3,806	125,000
Peeled root	415	12,800
Root bark	221	4,200
Soil	770	780
Aerial organs		
Outer leaf tip	4,869	98,790
Petiole half of leaf	4,023	82,540
Photosynthetic stem	1,179	31,300
Hard inner wood	502	55,900
Soft outer wood	1,269	34,580
Trunk bark	1,653	26,690
Soil	620	630

Nickel concentrations in the various 'insular' populations of *H. floribundus* were generally observed to decrease southwards (from 8,000 to 1,000 p.p.m.) as the annual rainfall increased from 7 inches to more than 30 inches. These 'ecotypes' can be recognised sometimes on morphology alone, and always by the use of organic (amino acids) and inorganic chemotaxonomy. The principal discriminators are N-acetyl ornithine, nickel and cobalt⁹. A study of intraplant distributions for nickel and other significant elements, shows that nickel concentrations increase from the roots through the rootstock, into the stems and reach maxima towards the leaf tips (Table 1). High nickel concentrations are also seen in seed capsules (1,500 p.p.m.), viable seeds (2,000 p.p.m.) and flowers. The mean concentration of nickel and cobalt in flowers (47 samples) is 5,003 p.p.m. and 8.7 p.p.m. respectively, whereas corresponding leaf concentrations are 3,665 p.p.m. and 24.8 p.p.m. It is evident that nickel is not excluded from reproductive tissue.

The maximum nickel concentration recorded to date is 1.6% (26% nickel in ash) in mature leaf tissue and this is in agreement with Cole⁸. Other elemental concentrations in leaf tissue, given as the mean of 217 samples in p.p.m. dry weight are: chromium 3, copper 5, cobalt 20, zinc 30, manganese 100, iron 370, sodium 1,100, magnesium 3,320, calcium 3,920 and potassium 8,000. Conventional atomic absorption was used to monitor the various elements. At these concentrations it was possible to measure nickel accurately in leaf segments weighing as little as 1 mg; mature leaves typically weighed 7 mg.

The Pearson product moment correlation coefficient (*r*) indicated several significant interelement relationships (Table 2). From those which are significant, it is evident that calcium is the only element to correlate strongly with nickel. This highly significant inverse relationship is observed in

TABLE 2 Interelement correlations (r) in *H. floribundus*

* Correlation significant, $P < 0.01$.

leaf, stem and wood tissue. Calcium was not measured in flowers but three significant correlations were observed, namely, nickel-manganese (negative), nickel-cobalt and cobalt-manganese. The effect of the inverse nickel-calcium relationship is to maintain the nickel plus calcium concentration at near constant levels in each of the three tissues examined. This suggests it is a substitution mechanism, and is supported by the recent findings of nickel in pectinates⁸.

More detailed studies, involving leaf tissue, indicate that nickel exists *in vivo* as a small (molecular weight less than 250) water-soluble cationic compound in agreement with a previous report¹. Histochemical staining (with dimethyl glyoxime) demonstrated a remarkable concentration of nickel in the epidermal layer which has been described elsewhere^{10,11}. The subcellular localisation of nickel was indicated to be at or near the epidermal cell walls, by means of an electron probe microanalyser¹². Leaching experiments were carried out in the glasshouse. These showed that simulated summer rain removed insignificant amounts (<0.5%) of nickel from aerial tissues, in spite of the epidermal concentration.

The accumulation of nickel in epidermal tissue of *H. floribundus* has been clearly demonstrated, but there is no evidence for a disposal mechanism. The leaves are perennial and nickel is not leached from them in significant amounts. This then raises the question, is nickel required by the plant? The essential role of nickel in *H. floribundus* was proposed⁷ on the basis of a statistical analysis of analytical data. Moore¹³ however commented that 'a physiological requirement for nickel' is difficult to explain. Cole⁸ listed the following alternatives to explain the causes of nickel accumulation by *H. floribundus*; (1) internal stress as the plant adjusts to more arid areas, (2) unrestricted transpiration and (3) a requirement for large quantities of nickel. A further suggestion¹³ is for localised selection pressure as the causal factor. There are, however, several features which can be merged to provide a hypothesis for nickel accumulation by *H. floribundus*. It is surely more than coincidence that the sole species in this arid region which does not display any apparent xeromorphic adaptation is also the only nickel accumulator. The regional correlation of increasing nickel concentrations with decreasing rainfall has been mentioned and I suggest that epidermal accumulation of nickel (where concentrations probably approach 5% or more, fresh weight) reduces cuticular transpiration and that in fact, nickel accumulation by *H. floribundus* is a xeromorphic adaptation. The origins of this idea are not new (see refs in ref. 14).

The need for nickel can account for the restriction of *H. floribundus* to nickeliferous soils in this arid environment. The present day disjunctive range of this species is the remnant of a former widespread distribution^{15,16} which retreated southwards with the onset of aridity. It is possible that the insular populations survived because they had evolved the ability to accumulate nickel, no doubt aided by polyploidy. Metal accumulation as a xeromorphic adaptation, may have application to accumulator plants in relatively arid regions elsewhere, and in particular to *Becium homblei*, the copper accumulator¹⁷ of south central Africa. Field experiments are now being set up in an attempt to establish the validity of this model. An initial approach will be to quantify the effect of nickel, cobalt and calcium on the drought resistance of *H. floribundus*.

I thank Dr R. R. Brooks and Professor P. J. Peterson for supervising early parts of this work, and also Drs G. A. Challis, P. F. Reay, A. Craig, W. D. Bennett and E. S. T. O'Driscoll for assistance.

book reviews

Coral, the living rock

Biology and Geology of Coral Reefs. Edited by O. A. Jones and B. Endean. Vol. 1 (Geology 1): pp. xvi+410; vol. 2 (Biology 1): pp. xxi+480. (Academic: New York and London, November 1973 and January 1974.) Vol. 1: \$28; vol. 2: \$42.50; £20.40.

THE appearance of these two volumes, to be followed by a like number, indicates the present interest in coral reefs. The great controversies of the last century concerning their origin, unresolved by the outcome of expeditions to Funafuti, were succeeded by a period of greater interest in living corals including taxonomy and the vexed significance of growth forms, work associated with the names of Mayor and Vaughan in the United States, of Stanley Gardiner in Britain and of Dutch workers in the then Netherlands Indies with the lone enquiring figure of Wood-Jones at Cocos-Keeling.

It was on the falling crest of this wave that in 1928 I took the Great Barrier Reef Expedition to Australia to study reefs as living systems but the only follow up came from the Tropical Biological Station established by the Japanese at Koror in the Palau Isles in 1935 and later destroyed in the war.

The present wave of interest was generated by mighty forces. In 1945 the United States Government decided to test atomic weapons at Bikini Atoll in the Marshall Isles. 'Operation Crossroads' in July 1946 was followed by other explosions until testing ceased in 1958. Accompanying operations involved major oceanographic surveys with wide ranging geological and geographical studies including the deep drillings on Eniwetok which, at long last, ended the controversy in Darwin's favour. Most detailed analyses of coral formations included taxonomy and ecology of corals.

But although attempts were made to estimate productivity, there was a singular lack of what may be described as intimate contact with living corals. This came with the work of T. F. Goreau in the Caribbean. Starting with calcification which he studied experimentally *in situ* below the surface, he proceeded with ecological analyses of coral formations and also revealed the unexpected richness of the Atlantic coral fauna. The greatest blow that coral reef studies have suffered was his premature death in 1970.

The editors of these volumes which summarise much of what has been achieved are connected with the Great Barrier Reef Committee at Brisbane which maintains an active centre for teaching and research on Heron Island in the Capricorn Group. When completed by the publication of two further volumes, the entire work will contain 46 contributions by 41 authors from 6 different countries. Unfortunately there is no indication of the contents of these future volumes so that one cannot judge how complete will be the final coverage.

There is little arrangement of chapters and no cross references between them; each must be read in isolation; however one knows the difficulties inherent in such composite works. The first, geological, volume which is essentially descriptive, contains an excellent account of Caribbean reefs by J. D. Milliman. His comparisons between these and Indo-Pacific reefs are illuminating and his description of sand cays as "slowly moving sand waves" is apt. There is no one so well qualified as Harry Ladd to write about Bikini and Eniwetok Atolls and everything affecting corals that occurred there. All will be grateful for this comprehensive statement.

The extensive recent work on reefs in the Indian Ocean, including Aldabra, which was covered by the symposium in 1971 is well summarised by David Stoddart. The reefs of French Polynesia (The Marquesas, Tuamotus, Society Islands, and the Austral Archipelago) with those of New Caledonia are described by J. P. Chevalier. F. W. Whitehouse deals with the reefs off New Guinea but strangely without illustrations: the one map referred to was certainly not in the copy I have received. Not surprisingly the volume ends with five chapters devoted to various aspects of the Great Barrier Reef, from the nature of its waters to geomorphology, structural and tectonic factors and sediments. There is a mass of useful information here—asking to be coordinated some day—although the maps illustrating distribution of sediments, some of them appearing isolated at the end of the book, are very difficult to understand; colour should have been used.

Much is made in the biological volume of microbial ecology and the pos-

sible—for it is as yet no more—significance of the microflora in coral nutrition. In a later chapter on marine antibiotics, interesting enough in itself, there seems to be no specific reference to scleractinian corals, only to gorgonids which are now, at any rate in the Caribbean, assuming unexpected significance as a source of prostoglandins.

Leonard Muscatine gives an expectedly judicial survey of the nutritional problem in hematyphic corals. But his extensive references to our work in 1928/29 is clear indication of how little, apart from studies on the zooxanthellae, to which he has contributed so notably, has since been done. J. H. Connell's chapter on coral ecology is also to be commended. He stresses the significance of interactions between coral colonies, a further indication (so badly needed) that, despite the immobile masses of lime they form, corals are living animals.

Peter Glynn contributes a long descriptive account of the ecology of coral reefs in the Caribbean which can usefully be read with Milliman's chapter in the other volume. G. J. Bakus provides what I take to be the fullest review to date of knowledge about tropical holothurians, so numerous in species and so ubiquitous on sandy areas of reefs. The last two chapters deal with that most destructive echinoderm, *Acanthaster planci*, adding to the rich literature on this now notorious, but biologically so interesting, starfish.

These volumes contain a wide range of information, the chapters inevitably varying widely in degree of relevance and mode of approach. They will be of real value to all engaged in aspects of coral reef research although they are hardly likely to draw anyone to the subject. They lack the breath of recent research which permeates the pages of the just completed "Coral Reef Project. Papers in Honor of Dr Thomas F. Goreau 1924–1970" (*Bull. mar. Sci.*, Miami, vol. 23) which should be seen by all who are interested in the volumes under review. The two further volumes will soon, one hopes, be available. The editors somewhat strangely dedicate the work in part to themselves but, more significantly, add the name of H. C. Richards, at one time Professor of Geology at Brisbane, to whom I gladly offer a personal tribute.

Studies on Excitation and Inhibition in the Retina

EDITED BY F. RATLIFF

April 1974: 688 pages: £8.50

For nearly half a century, Nobel Laureate H. Keffer Hartline has conducted research on vision and the retina. His studies have elucidated numerous fundamental principles of retinal physiology which, over the years, have provided the foundations for many advances in the neurophysiology of vision. This collection of papers from Professor Hartline's laboratory, together with the specially written introductory sections, provide for the first time a full account of the development of this subject, and show how Hartline's particular mathematical-experimental approach is being adopted widely in the analysis of complex neural networks.

Plant Viruses

K. M. SMITH F.R.S.

Fifth edition, March 1974: 224 pages: £3.30 Science Paperback £1.30

This new edition has been expanded to cover the present knowledge on the whole field of plant viruses. So far as it is possible in a book of this size, all the latest developments in the subject are included, such as the assembly of some virus particles, the discovery of the 'viroids', the latest information on the transmission of viruses by fungi and the most recent work in the way that viruses affect the fungi and also the algae.

Telecommunications

J. BROWN

Second edition, 1974: 400 pages £5.50 Science Paperback £3.00

A Review of the Principles of Electrical and Electronic Engineering

To be published in four volumes

EDITED BY L. SOLYMAR

Volume 1: Principles of Heavy Current Engineering

February 1974: 124 pages: £1.65.

Volume 2: From Circuits to Computers

February 1974: 192 pages: £2.50

Further details on these titles and a list of stockists available from the publishers on request.

Colonial animals

Animal Colonies: Development and Function Through Time. Edited by Richard S. Boardman, Alan H. Cheetham, and William A. Oliver, jun. Pp. xii+603. (Dowden, Hutchinson and Ross: Stroudberg, Penn.; Wiley: Chichester; December 1973.) £17.50.

THIS book, the outcome of a symposium held in Washington in 1971, consists of a series of papers which attempt to analyse the basic nature of metazoan colonies and to provide new information on the development and function of key groups of colonial animals, with emphasis on those with good fossil records. The various papers illustrate two common themes as regards the definition of coloniality: members of the colony must be physically connected and they must have common ancestry through a sexual reproduction; social insects and certain 'colonial' forms are therefore excluded. The assumption of genetic constancy allows a direct evaluation of other factors controlling morphological and physiological differences within the colony, such as ontogeny, polymorphism and environment.

Attention is restricted to four groups of animals, the coelenterates, bryozoans, graptolites and sponges (whose interpretation as solitary or colonial animals remains controversial). The treatment of these groups, however, can hardly be described as balanced. Thus the bryozoans cover 42% of the papers and 55% of the pages whereas the unfortunate sponges get only 11% of the papers and 6% of the pages.

With regard to the individual contributions of authors, it is difficult to make generalisations, because they range from lengthy, comprehensive reviews to short morphological, physiological or ecological accounts of individual species or even, in a couple of cases, to one page abstracts. Most of the material can only be adequately evaluated by a specialist in the particular groups concerned, but several papers stand out as of more general interest. For instance, Coates and Oliver examine the kinds and levels of integration in fossil and living zoantharian corals and discuss the evolution of coloniality in relation to the formation of reefs. Boardman and Cheetham, in the longest paper in the volume, evaluate the pattern of increasing structural and functional integration of bryozoans through geological time, and infer the operation of mosaic evolution. Schopf propounds and confirms to his satisfaction a model relating the degree of polymorphism in bryozoans to stability of the environment. Urbanek discusses the organisation of graptolite colonies, which are interpreted in terms of physiological gradients and genetics and in

the broader context of evolution. Although the book as a whole has a palaeontological bias there is a full coverage of living organisms and some papers deal exclusively with these.

Illustrations are abundant, with 140 line drawings and more than 200 photographs, and the production is good. The book can be recommended to all professional palaeontologists and zoologists interested in colonial animals.

A. HALLAM

Iron to carry electrons

Iron-Sulfur Proteins. Vol. 1: Biological Properties; vol. 2: Molecular Properties. Edited by Walter Lovenberg. Vol. 1: pp. xiii+385; vol. 2: pp. xiii+343. (Molecular Biology: An International Series of Monographs and Textbooks.) (Academic: New York and London, November 1973 and January 1974.) Vol. 1: \$33; vol. 2: \$29.

THE excitements and developments during barely two decades of research on iron-sulphur proteins make compulsive reading for those in the field and possibly to those who are entering it—and perhaps also to students who want to find out how research has been pursued and what knowledge has been accumulated now (or rather, about two years ago). The name iron-sulphur proteins applies to iron proteins in which the iron is liganded to sulphur—it is non-haem iron. The iron-sulphur proteins seem to be ubiquitous from the "primitive", obligate, anaerobic bacteria to higher plants and animals. They mainly function as electron carriers at very low redox potentials (although this can be altered) in most of the principle reactions sustaining life such as photosynthesis, nitrogen fixation and electron transport in subcellular membrane systems.

Volume 1 contains an excellent chapter on nomenclature and history by H. Beinert which puts the field in perspective and shows how an apparently new field has been based on unrelated endeavours in three fields: photoreactions in chloroplasts, previously unaccounted for protein-bound iron in mammalian systems, and nitrogen fixation in bacteria. Now that non-destructive and specific methods of analysis such as ESR and ENDOR (with rapid freezing techniques), NMR, and Mössbauer spectroscopy are available for studying the iron-sulphur proteins (which are much more labile than, for example, cytochromes) their structures and roles are being reported frequently and the field is spreading rapidly into many aspects of biochemistry and molecular biology.

The other nine chapters of volume 1 deal with the properties and roles of

iron-sulphur proteins in diverse reactions of bacteria, nitrogen fixation (where model compounds with biological activity are being extensively pursued), photosynthesis, carbon fixation, mono-oxygenase reactions, hydrocarbon hydroxylations, steroid hydroxylation in adrenals, and flavoprotein dehydrogenases and hydroxylases.

The wealth of information now available on iron-sulphur proteins and their roles in the above types of reactions is very well presented by the authors and well edited by Lovenberg to minimise overlap. There is a comprehensive subject and author index.

For the second volume, suffice it to quote the editor's preface: it "provides an in-depth analysis of the chemical and physical properties of many of the iron-sulphur proteins. Particular emphasis is placed on the theory and use of physicochemical techniques in the study of metalloproteins".

This volume thus provides the important companion to the first where biological properties were discussed. The importance of the biological integrity of the protein when its physicochemical properties are being investigated is rightly stressed, as this point has often been neglected in the past when physical techniques have been applied to biological compounds. This is especially important with the generally quite labile active centre of iron-sulphur proteins.

There are fascinating sections on the evolution and genetics of iron-sulphur proteins, how to build up the X-ray structure of rubredoxin, the theory and practise of EPR and ENDOR, and many comprehensive tables of useful data.

It is such a pity that it inevitably takes so long for a book to reach the desks of researchers in such rapidly developing fields; but there is now a comprehensive summary by specific workers in the field up to 1972 (addenda have been added to a number of chapters in both volumes)—and one must be thankful for this! The cost of the two volumes is very high but I hope that this will not deter anyone from having the books constantly at hand whenever referring to iron-sulphur proteins.

D. O. HALL

The tektite mystery

Tektites. Edited by Virgil E. Barnes and Mildred A. Barnes. Pp. xv+445. (Benchmark papers in Geology.) (Downden, Hutchinson and Ross: Stroudberg, Penn.; Wiley: Chichester, 1973.) £10.

As if problems recognised to be geological were not numerous enough, tektites seem to present an entirely separate mystery. Strewn fields of these strange objects are known at eight restricted

sites scattered over the globe. They mostly weigh tens of grams, and consist of highly refractory compounds, about 80% silica for example. The oldest are the bediasites at about 40 million years, and the australites youngest at under a million years. They bear little discoverable relation to their surroundings, yet they are found practically where they must have originally fallen from the sky.

Held together by surface tension just before they finally come through the high atmosphere, the tektites are there distorted into numerous aerodynamic forms: some australites starting quite spherical ablate to characteristic button-like shapes, which can and have been precisely reproduced in wind-tunnels. Remarkable indeed is the property that within every cubic centimetre of a tektite are embedded hundreds of micron-sized intrusions, while minute occluded gas bubbles are at pressures of order only a thousandth of an atmosphere.

This book consists of 45 individual papers, grouped by topics each with introductory editorial comments, and provides a volume of fascinating interest. It must cover everything known and conjectured about tektites, except perhaps a satisfactory answer to the great problem of their origin. Possible relevance to solving the re-entry problem (for spacecraft) intensified their study at that time, and for a decade a source from meteoritic lunar impacts was widely supported as the most likely answer. But the moon has since been more closely examined, with nothing much hopeful for tektites found thereon, and a terrestrial source now seems inescapable.

But they cannot result immediately from impact, and the only possibility would seem that they represent a far more remote end product of terrestrial meteoritic impacts, of sufficient violence to gasify huge amounts of surface rocks and project a vigorously expanding cloud from the resulting explosion. In cooling, the most refractory substances would condense out, and sprayed in all directions, their trajectories round the Earth would converge again to form a heated and melted accretion stream descending at the antipodal region. Fragmenting under terrestrial acceleration into solidifying droplets, these would continue to be bombarded for a time by further tiny solid particles converging to the stream.

All this may seem highly improbable, but it would explain why no tektites are found in the whole Soviet Union (one sixth the land surface) since this lies opposite much of the watery Pacific, whereas the known fields are all effectively antipodal to land masses. And if this (very briefly) is not how they were formed, one can only ask what other mechanism can be suggested?

R. A. LYTTLETON

Stave off starvation

Nutritive Value of Triticale Protein (and the Proteins of Wheat and Rye). By Joseph H. Hulse and Evangeline M. Laing. Pp. 183. (International Development Research Center: Ottawa, 1974. \$7.50.

THOSE of us who are concerned about the long-range prospects for world food supplies have for many years been grumbling that we depend for almost all our food on plant species selected by primitive man—or more probably woman. The first break with this unseemly dependence on the past comes, not from the domestication of a new wild species, but from the creation of a new species. This is triticale: a hybrid of wheat and rye (*Triticum x Secale*). Ostensibly, this is a book about it. Unfortunately, the authors have spread themselves over the whole subject of the properties and manner of use of wheat and rye, and the results of adding supplements such as amino acids, soya, fish and microbial products to them. Triticale gets rather lost; less than a third of the book deals specifically with it. Mainly, the authors have simply copied out their index cards after rough classification. Incompatible conclusions appear side by side without comment, though some reconciliation is attempted in a 17-page introductory survey.

Triticale can be made by crossing several subspecies of wheat and rye; it is therefore a genus rather than a species. Sterile crosses were made in 1875, colchicine-induced polyploidy made them partially fertile in 1937. Since then many fully fertile strains have been produced, compared and standardised. In comparable conditions the better strains seem to give larger yields than wheat; an experiment is quoted in which triticale yielded 8.3 and wheat 7.2 tons per hectare. As with wheat and rye, the protein content of the grain varies with cultural conditions, but triticale seems usually to surpass the other two. The amino acid analyses quoted are by no means concordant. Before the statement that triticale contains more lysine than wheat is accepted, we should be told how many analyses were done on each sample, how many samples from the same crop were taken, and how amino acid composition is affected by cultural conditions. Amino acid analysis is not such a foolproof process as it is often assumed to be.

Many of the properties of triticale are intermediate between those of its parents. It contains less resorcinol than rye and is less susceptible to ergot, but it is not as suitable for bread-making as wheat though a mixture of flours is satisfactory. There seems to be no evidence on the phytic acid or trypsin

inhibitors in triticale; in spite of this, the authors devote four pages to these components of wheat and rye. Triticale is a new crop on which much more research and development are needed. Its superiority to its parents is not yet unequivocally established but is probable. It seems clear that triticale is potentially a valuable crop: someone ought to write a book specifically about it.

Polar humans

Polar Human Biology. (Proceedings of the SCAR/IUPS/IUBS Symposium on Human Biology and Medicine in the Antarctic.) Edited by O. G. Edholm and E. K. E. Gunderson. Pp. xii+443. (Heinemann: London, November 1973.) £6.00.

THE symposium from which this book resulted took place in Cambridge during September, 1972. The editors are to be congratulated on producing it within a reasonable time and the publishers have provided an attractive format and a price which is not excessive. Certainly, the book deserves to be read widely, for it describes the state of the art of research into polar human biology and medicine at a time when great advances have been and are being made.

The book falls naturally into five sections. An initial series of reviews of the individual contributions to Antarctic research by the several countries concerned is followed by two papers on dental problems and a larger section on virological and immunological research. Next follow a group of papers on various aspects of thermal adaptation, activity patterns and circadian rhythms. The book ends with a large section devoted to psychological and social problems of life under the severe conditions which constitute the polar environment.

As might be expected with such a large range of subjects, the treatment is very uneven. Several of the papers are either anecdotal or present largely unanalysed sick-report data. Though of practical interest they seem out of place here. On the other hand a few papers seem destined to become classics in the study of man at extreme latitudes. In particular the two papers of Shephard and his collaborators Godin and Rode seem to me to combine all that is excellent in a multidisciplinary study of the response of the Eskimo to his rapidly changing pattern of life. Roger's paper on cold adaptation in members of the Commonwealth Trans-Antarctic Expedition of 1958 is equally admirable—indeed, perhaps more so, since the conditions of work must have been much more severe. His conclusion—that general biological adaptation to severe cold does not occur—is interesting to say the least!

The importance of psychological and cultural factors in polar adaptation is rightly stressed. Much of it is of an applied nature, in particular for personal selection, and several of the papers reflect this interest. Again, though, one wonders if this book is the right vehicle for such reports.

Though the book contains much that is good and some things which are really excellent, it is impossible to escape the general conclusion that the international organisation of polar (and particularly Antarctic) research in human biology is in a pretty anarchic state. A good many papers show considerable areas of overlap of topic and similarity of methodology and it seems sad that the impetus of the International Biological Programme towards cooperation and standardisation seems to have petered out in the far south. I hope, though, that this book will be a spur to the greater integration of research. If this happens the enormous devotion and self sacrifice of many of the scientists, working often in an environment as lethal as any in the world, will be fully rewarded.

E. J. CLEGG

Biological information

Elementary Principles of Probability and Information. By R. F. Wrighton. Pp. viii+91. (Academic: London and New York, January 1974.) £1.95; \$5.50.

THE author is primarily concerned with the applications of statistical inference and information theory to the biological sciences. He complains that biologists are 'currently witnessing a resurgence of anthropomorphism as information notions percolate into biological enquiry conceived at the molecular level'. He foresees that present macro-theories, derived essentially from 'purely subjective interpretations of probability' and applied to information processes of macro-systems in which it is always possible to distinguish between 'the label and the labelled', will break down at or near the molecular level.

At first sight, his programme seems to imply a direct though difficult reduction of biology to physics. But the programme is even more fundamental than that. In his last chapter, noting that anthropomorphic heresies, in the form of traces of communication notions, pervade both quantum and relativity theories, the author looks forward to a 'complete fusion of information theory with quantum theory rather than to any less intimate association'. He is therefore claiming that 'the much closer physical analysis he seeks of biological processes could solve some of the epistemological problems of modern physics. That is an ambitious programme. Is it possible for man to establish a science from which all anthropomorphic residues

Corrosion of metals research 1924-1968

This book, written in a semi-popular style, by Dr Wormwell of the National Physical Laboratory, is intended for people with an interest in corrosion and its prevention. It is a modest contribution to the history of government science and offers an example of what can be achieved by a long-maintained team working in one broad area of endeavour.

£1.65 (£1.72)

A code of practice for the detailed statement of accuracy

The main purpose of this Code of Practice, prepared by the National Physical Laboratory, is to put forward recommendations as to how uncertainty can be expressed so as to avoid ambiguity, and discusses some of the ways in which estimates of uncertainty can be derived from individual measurements.

£1.05 (£1.10)

Government publications can be bought from the Government bookshops in London (post orders to PO Box 569, SE1 9NH), Edinburgh, Cardiff, Belfast, Manchester, Birmingham and Bristol, or through agents and booksellers. The Bookseller section of Yellow Pages gives your nearest stockist.

HMSO BOOKS

are completely eliminated? If so, then at least we have to begin by identifying those residues that can be discerned and considering what might be done about them. And that is what the author attempts to do.

Unfortunately, the reader finds himself embarking on this fundamental programme without being clearly informed about where he is being led. The seven chapters discuss familiar topics in an unfamiliar way—randomness, the basic Shannon model, noise, inverse problems in probability, sampling techniques, and so on. These topics, dealt with in terms of elementary mathematics, enable the author to air the serious problems he has in mind. But it is only slowly and with much re-reading that the reader builds up any coherent picture of the author's objectives. So it is difficult to see to what readers this book is addressed. Those seeking techniques for immediate practical application will find none: those interested in the fundamental problems discussed will be misled by the title and would not expect so serious a programme to be presented in this form.

But the author's ideas are stimulating. Information concepts derived from telecommunications and other physical systems do seem to be inadequate for enquiry into the processes of 'information transfer' on which all living organisms depend. B. C. BROOKES

matters arising

Temperature cycle in the North Pacific

SIR,—I suggest that the evidence presented by Favorite and McLain¹ for trans-Pacific displacement of temperature anomalies at the ocean surface, is far from conclusive and that there is no evidence that waves progress around the North Pacific gyre.

The eastward advance of the anomalies across the Pacific Ocean from 1954 to 1960 is not immediately obvious or orderly. An explanation of the widespread warming in 1955 of the eastern Pacific between 35°N and 40°N, in terms of an eastward displacement of the maximum, implies a rate of advance of some 15 km d⁻¹. This is about three times greater than the generally accepted pattern of geostrophic flow, which is slightly more than 5 km d⁻¹. Similarly, the rate of advance of the positive anomaly from the western side to the eastern side of the ocean from 1956 to 1957 would have been some 15–20 km d⁻¹. Conversely, there was very little change from 1958 to 1960, when, according to the proposed hypothesis, the negative anomaly should have progressed eastwards to embrace the western coast of North America. Another discrepancy is the westward movement of the negative anomaly in the eastern Pacific from 1955 to 1956.

If the rate of advance of the temperature anomalies, indicated by geostrophic calculations, is slightly more than 5 km d⁻¹ and the circumference of the North Pacific gyre is some 18,000 km, then the time required for a water parcel to complete one circuit would be nearer 1 yr than the 6 yr suggested.

Suggestions that there is evidence of

the temperature cycle as far back as 1930 in the western subarctic region carry little weight in view of the statement that "it is difficult to establish normal conditions at any time or place that would allow the detection of anomalous conditions in a water column at the western side of the ocean."

A simpler explanation of the 5–6 yr cycle in sea surface temperature anomalies in the North Pacific is that heating and cooling occur *in situ*. Baur² has shown that the intensity of the solar beam undergoes a double systematic variation, amounting to 0.5%, within the 11-yr sunspot cycle, with primary maximum strength at about 0.4 of the rising phase and a secondary maximum at about 0.6 of the declining phase of solar disturbance; a sharp minimum of the solar constant occurs just before sunspot minimum, with a secondary minimum at about 0.6 of the rising phase. These variations of the solar constant have been applied to the known years of sunspot extremes from 1950 to 1968 (ref. 3). Figure 1 shows that there is a high positive correlation between sea surface temperature anomalies in the North Pacific, and fluctuations of the solar constant.

There are other well documented relationships between variations in the output of solar energy and meteorological and climatological phenomena. The height of the tropopause at Leopoldville, near the equator, rose by more than 1 km between the 1954 solar minimum and the 1957 maximum (ref. 4). This could be interpreted as resulting from a strengthening of the ascending branch of the Hadley cell associated with greater energy transfers in the atmosphere at the time of increasing output of solar radiation. In East Africa, the level of Lake Victoria was highest in 1952, 1957, and 1964, some 1–2 yr after maxima³ of the solar constant. Again, an increase in surface heating at the time of maximum solar output would lead to an increase in convection and thus to an increased tropical rainfall. In European Russia there were sharp fluctuations in the mean temperature from month to month at times when solar activity was increasing in 1956–57⁵ and in 1967–69³. The strength of the westerlies over New Zealand tended to increase about 10 months after rises of solar activity (B. N. Parker, unpublished information). More generally, large fluctuations of Baur's solar index⁶ in the extreme sunspot

cycles since about 1940 coincide with decades of increased variability of wind circulation, with falling values of indices of the strength of the zonal windstreams and with increasing variance of climatic elements in many parts of the world³. Processes by which solar activity may influence weather and climate are discussed by Lamb³.

Thus, the 5–6 yr temperature cycle in the North Pacific could possibly be caused by systematic variations of surface heating resulting from variations in the output of solar energy during the 11-year sunspot cycle. This simple pattern would be modified by ocean-atmosphere interactions and quasistationary waves, to produce regional variations in the timing of the maxima and minima. The geographical distribution of temperature anomalies at each phase of the sunspot cycle would then not be expected to be the same in each cycle. In fact the coherence evident during the 1958–60 cycle was not readily apparent during 1948–52 or 1961–67 (ref. 1). It is to be expected that the effects of these variations in the output of solar energy should also be evident in temperature anomalies in other oceans.

Yours faithfully,

Macromolecular structures for undergraduates

MEYER¹ and Feldman *et al.*² describe the use of computer displays for the three-dimensional study of macromolecular structures. They suggest that, in the near future, such systems will be available for teaching purposes. As students we should like to point out that computer graphics have disadvantages for teaching in England, and that there are now available molecular models which may be used to emphasise different aspects of structure in an immediately

Fig. 1 Myoglobin stereopair built from Biobits model system. The helices, N- and C-terminal ends, haem pockets, types of R groups and their location on the surface or within the interior of the molecule are readily and immediately obvious.

comprehensible manner. One of these systems³ in particular makes possible the building of a complete macromolecular structure such as myoglobin within a framework 60 × 60 × 30 cm (Fig. 1) and in one to two days.

One problem in the use of computer graphics is the cost of installing and running the apparatus. Another is that students would need specialised training to use it. Models have the advantages that they are built by the student, can be handled and viewed from all sides, and are portable. Models display more than adequately for the undergraduate the features of families of macromolecules: there seems little point in listing the features of molecule after molecule in a computer display.

Biobits models for proteins and nucleic acids are available from Capital

Biotechnic Developments Ltd., 66A Churchfield Road, London W3, United Kingdom, and from Ealing Corporation, 2225 Massachusetts Avenue, Cambridge, Massachusetts 02140. With these models we have been able to build accurate scale models of myoglobin, carboxypeptidase A, LDH monomer and other proteins within a day or two of receiving the X-ray data. Indeed we have probably built and studied a wider range of proteins than any other undergraduates in England including those in the major X-ray crystallographic departments.

We appreciate the tremendous value of computer graphics: the system can, for example, overlay structures of two molecules for direct comparison in a manner which models could never do. But we hope that before any depart-

ment switches to this complex and expensive system it will reconsider the very great advantages of real models.
